Executive Government

Wolfgang C Müller, University of Vienna, Vienna, Austria

Abstract

In its modern understanding, executive government exists only after the successful separation of powers and the establishment of parliaments. The various types of executives are defined mainly by their method of creation and relations with the legislature. Constitutional and other rules' silence regarding them leaves much of the executive government's internal life for effective self-organization by incumbents. Institutional rules, functional requirements, and the party-political support base of governments lead to distinct models of executive government. The relative strength of government is largely rooted in institutional and party-political factors. Even weak governments tend to be the most important single actors in democratic states. The study of executive government's actual functioning, deeds, and omissions still lacks what other subfields of political science have achieved, which is partly due to the specifics of the research topic.

Executive Government

'Executive government' refers to the political part of the executive branch (which, in turn, is to be distinguished from the legislative and the judiciary branches). There is, however, no easy answer as to where precisely to draw the boundaries between the political part and the remainder of the executive.

The unique task of executive government is to govern the country. Governing means ruling, providing leadership, and transforming political will into public policy. It is not, as the term 'executive' might suggest, just implementing laws passed by the legislature. Rather, governing means executive governments have a strong imprint on the laws passed during their reign and, more generally, exercise overall control over a country, and determine its direction. Even weak governments are the most important single political actor in most regimes.

Origin

While government has existed ever since mankind has organized states (Finer, 1997), executive government in the modern sense emerged through the piecemeal split-off of state functions from a traditionally undivided central government (mostly a monarch) (King, 1975). In order to limit the government's power, judicial functions were transferred to courts and legislative functions to parliaments. This process began in twelfth- and thirteenth-century England. It had many national variations and in Europe was not completed before the twentieth century. The constitutional doctrine of the separation of powers – as developed first and foremost by Locke, Montesquieu, and Madison – provided a normative justification for the separation of legislative, judicial, and executive institutions, which was seen to guarantee liberty and justice (Vile, 1967).

In practice, the state functions were never as neatly separated as envisaged by normative theorists. The executive has retained important legislative functions, in particular, drafting legislation and issuing government decrees and ordinances (Carey and Shugart, 1998). With the full democratization of polities and the establishment of political parties as the main mechanism to structure elections and coordinate incumbents, executives have gained almost a monopoly in law-making in parliamentary systems. In presidential systems, this is not true to the same extent, but executives also exert large influence on legislation by proposing policies and exercising veto rights.

As nondemocratic regimes typically mimic the institutions of democratic ones, executive government here too prevails. Yet, separation of power exists only on paper, allowing holders of political power to intervene in all types of decisions. The real power holders often assume leading positions in executive government, but it may also be that the real center of power is elsewhere. Then executive government may be subject to the orders of the military leadership, the state party presidium, or a religious leader. Nondemocratic regimes thus show a great variety with regard to executive government and will not be further discussed here.

Types of Executive Governments

The executive's nature and executive–legislative relations have traditionally been crucial for the classification of regime types. In the contemporary world, the most important regime types are (1) presidential systems, (2) parliamentary or cabinet systems, and (3) semi-presidential systems. In presidential systems, the chief executive is directly elected for a fixed term and appoints and dismisses the members of his/her government. These cannot be dismissed by the legislature. In a parliamentary or cabinet system, the executive, whether appointed by a head of state or directly created by parliament, remains fully accountable to parliament. Although the prime minister typically has a gatekeeper function, at least through formal control of access to and dismissal from the cabinet, formal decision-making is collective for important matters. Less important matters fall under the jurisdiction of individual cabinet ministers. A semi-presidential system combines a directly elected and powerful head of state with a prime minister and government who are accountable to parliament.

There is, however, no full agreement on how to define these regime types precisely and whether the semi-presidential type indeed constitutes a distinct regime type (Sartori, 1997; Lijphart, 2012; Elgie, 1999; Strøm et al., 2003). In addition to

these widespread regime types, assembly government, collegial (or 'directorate') government, and government with a directly elected prime minister can be identified. In assembly government, decisions are indeed made in parliament, and the cabinet is not more than the assembly's executive secretariat. With the exception of the French Third Republic, it has existed in its pure form for only short periods, often after a revolutionary regime change. There is only one case of collegial (or 'directorate') government – Switzerland. There, the cabinet is elected by parliament for a fixed term, i.e., it is not accountable to the assembly and it is fully collegial; even the chairmanship rotates among its members. Only one case of government with a directly elected prime minister has existed (Israel 1996–2003); this is generally considered a failed constitutional experiment (Kretzmer, 2006).

While these five first-listed regime types have since long belonged to the arsenal of political science, a new demand for constitutional engineering (which came with the new waves of democratization of the 1970s and particularly the 1980s and 1990s) and the new theoretical research agenda of neo-institutionalism have spawned new interest in them (Weaver and Rockman, 1993; Linz and Valenzuela, 1994; Moe and Caldwell, 1994; Sartori, 1997; Lijphart, 2012; Strøm et al., 2003). The question that is common to constitutional engineers and neo-institutional theorists is: What types of output are these regime types likely to generate in terms of the maintenance of democracy, accountability of public officials, and public policy? Each regime type is likely to maximize some effects, but at the costs of others. Hence, the appropriateness of regime types and of specific institutions within the confines of a regime type depends on the most important challenges a polity faces (Sartori, 1997).

The Study of Executive Government

Research on the political executive is a large and increasingly diverse field, including studies on individual offices (such as presidents, prime ministers, cabinet ministers, and top bureaucrats), and government institutions and processes (including informal ones).

Classic institutionalism had not much to say about the executive per se. The executive was mainly characterized through its relations with other state institutions. These relations, in turn, were important for classifying regime types. The bulk of research on the executive, however, has always been historic-qualitative, building on memoires, media reports, the occasional interview, private papers of former members of the executive, and other archival sources. Notwithstanding some impressive individual scholarship, this research has traditionally suffered from three problems. First, with the exception of the US presidency, research on the executive was rare, particularly given its subject's relevance and compared with the attention other political phenomena have received. Secondly, compared with other research fields, fewer attempts at original and systematic data collection were made in executive studies. This partly reflects the research object's properties, namely small numbers (of chief executives, cabinets, cabinet ministers, and top bureaucrats) and limited access (because they are busy people with greater secrecy requirements). Finally, much research on the executive had also been quite idiosyncratic and more rooted in national peculiarities than, for instance, research on electoral behavior or parliaments.

Although these three points are still valid to some extent, executive research has made important achievements in recent decades. First, more countries and individual governments have been subjected to studies in the historic-qualitative tradition, and consequently, the pool of recorded qualitative information has been greatly extended (from the Pacific to Eastern Europe, see, e.g., Hayao, 1993; Blondel et al., 2007). While chief executives have always received much attention (e.g., Rose and Suleiman, 1980; Helms, 2005; Poguntke and Webb, 2005), more recently, the perspective on executive government has become broader and less leader-centered (e.g., Blondel and Müller-Rommel, 1993; Laver and Shepsle, 1994; Strøm et al., 2008). Secondly, the best country studies have become much more rigorous, building on, for instance, systematic interviews with former cabinet ministers (e.g., Burch and Holliday, 1996), ethnographic observation of political actors at work combined with interviews (Rhodes, 2011), and theory-guided case studies of executive decisions (e.g., Rhodes and Dunleavy, 1995). Third, quantitative data and statistical methods have gained further grounds in the study of executive government (with regard to parliamentary systems, this mostly applies to elite and coalition studies; for research on the US presidency, see Edwards et al., 2009; Edwards and Howell, 2009). Finally, executive studies have become more theory-guided and comparative. At the forefront of theory-inspired research, agency theory has been applied to executive–legislative relations (e.g., Epstein and O'Halloran, 1999; Strøm et al., 2003) and intra-executive relations (e.g., Andeweg, 2000). The fact that country expertise is probably more crucial here than in any other subdiscipline is reflected by much cross-national collaborative work. However, comparative work including executives from both sides of the Atlantic is still rare (Weaver and Rockman, 1993; Weller et al., 1997).

Given the centrality of executive government, it is often hard to disentangle the relevant research from the study of the country's governance *tout court*. Consequently, much research devoted to the study of other political phenomena intersects and is also relevant to understand what executive governments do and the causes and consequences of government action (e.g., research on parliaments, political parties, interest groups, business elites, the mass media, political agendas, and public policy).

The Organization and Functioning of Executive Government

Constitutional documents typically omit rules about the internal working and decision-making of government, and little is fixed by other formal rules. Such omission is not accidental but aims at providing current governmental actors to conceive their internal organization and decision-making modes according to their needs. Similar challenges to incumbents have often established conventions on how to organize and run executive governments typical to particular countries or regimes. But the executive can change such conventions by unilateral action, and, if gradual, such change may not be immediately recognized by the outside observer.

Ambitious politicians aim for executive government office not only because such positions are attractive as such, but also because they provide incumbents with a unique chance to make policy in line with their preferences. Even defending the status quo often requires government actions. While a portion of issues on the government agenda are thus due to the incumbents' desire to make policy, many more result from other actors' successful agenda-setting efforts, routine administrative processes, secular trends, and external events (including natural disaster, terrorist attacks, foreign government action, and market turbulence). Again, being able to exert strong influence on policy responses to such externally imposed issues is an executive government's privilege.

Effective policy-making requires collecting and evaluating information on the issues at stake, conceptualizing and vetting policy options, developing workable policy instruments (such as regulation, incentive systems, the provision of public services, or diplomatic moves), providing financial means for the resulting costs, mobilizing the required political and societal support, and making sure that the implementation does not suffer from bureaucratic drift or ignorance and resistance of target groups. Policy failure can result from any of these. Governing is thus a highly challenging task. To fulfill it, executive government adapts and builds new internal structures and processes. It mobilizes expertise and manpower to support the thin layer of career politicians in executive government by drawing on reorganizing and staffing the permanent bureaucracy (Lewis, 2008), recruiting political appointees (who leave office with their political masters), and employing external advisors on voluntary or professional basis. With the exception of the US presidency (e.g., Burke, 2000; Warshaw, 2004), research on executive government support structures is largely scattered in national language publications.

Depending on the regime type and the current balance of political forces, executive governments face different needs in terms of mobilizing support. One target is clearly the legislature, the support of which is required to pass legislation and, in case of parliamentary and semi-presidential regimes, to ensure the survival of the cabinet; it constitutes a particular challenge in multiparty systems and for minority and coalition governments. The literature on coalition governance has identified and analyzed a number of mechanisms employed by government parties to ensure the continued support of the cabinet parties and the legislature. These include written formal coalition agreements, the use of existing structures such as parliamentary committees and watchdog junior ministers to check the office behavior of the partners, and the establishment of extraconstitutional bodies such as coalition committees to force consensus and to manage and resolve conflict if it arises (Martin and Vanberg, 2011; Müller and Strøm, 2000; Strøm et al., 2008, 2010). While much remains to be done in describing and analyzing individual mechanisms of coalition governance, countries, and periods, the theoretical agenda is moving toward the analysis of coalition governance to issues of their overall design, to focus on the entire architecture of interparty institutions and mechanisms.

Another dimension of support is derived from mass media and the general electorate. Basically, maintaining the latter is crucial in any democracy, and mass media support can be instrumental. Both can also be helpful to overcome resistance within government parties and from the legislature. The study of presidential government has long included this dimension of executive leadership (Edwards, 2009), and it also figures prominently in the analyses of 'presidentialized' prime ministers such as Tony Blair and Gerhard Schröder.

To capture the actual functioning of executive government, political science has established a number of descriptive models. These are partly derived from the constitutional order but try to highlight how the institutional features and political forces interact and how executive government arrives at decisions. The following models thus capture to what extent actors are typically able to determine outcomes of government decision-making processes compared with other participants. They were initially developed with the background of the archetypal cases of presidential and parliamentary government – the US and the UK – and subsequently applied to other cases. As these cases are partly more complex, they have given reason for conceptual refinement.

Elgie (1997), for instance, distinguishes monocratic (presidential, prime ministerial), collective (cabinet), ministerial, and shared government (with an in-group of executive government members in the driving seat). Any of these can also manifest itself as bureaucratic government (where politicians only maintain the façade but *de facto* abdicate and leave real decision-making to bureaucrats). Finally, segmented government means that different modes may coexist, each one prevailing in one or more policy areas.

These government modes describe how executive government decides at given times. They are likely to change along with important structural and contextual parameters. Single-party cabinets, for instance, are likely to adopt the prime ministerial government mode, but coalition cabinets are not. Some changes are of more long-term nature. The authors identifying trends toward prime ministerial government or presidentialization have identified crucial changes in the tasks of the state, the mass media environment, international embedding, cleavage structures, and electoral politics as factors driving this process (Poguntke and Webb, 2005). Yet, such structural factors only provide opportunities and expectations: Prime ministerial government also requires suitable personalities, who are not always available. The ministerial government mode (Laver and Shepsle, 1994, 1996), where real power rests with individual ministers, and cabinet approval remains purely formal, is rooted in the institutional prerogatives of ministers in their policy domain, partisan interest and power sharing in coalition governments, and the impossibility to exercise full control for a single center of authority in single-party government.

Segmented government implies that each cabinet is likely to handle issues differently according to its policy domain (Andeweg, 1997; Elgie, 1997). Factors such as the policy substance (degree of technicality, financial resources involved), nature of the policy community, pressure on government from parties and interest groups, mass media interest, and the electoral benefits to reap or the damage inflicted if things go wrong can differ largely. This suggests different ways to handle these issues. Currently, 'segmented government' is an interesting idea based on some largely anecdotal evidence from a few countries that still might merit theoretical elaboration.

The frequently asserted transformation of cabinet government into prime ministerial government and/or ministerial government suggests some long-term change between models of government. This becomes more complex when further short-term situational factors are considered and routine decision-making is distinguished from decision-making in situations of crisis (e.g., Allison, 1971; Boin et al., 2005).

New research frontiers on executive government are defined by the increasing internationalization of governance. On the one hand, this means the building of regional centers of integration. The most important and deeply structured one is the European Union. Thus, executive studies have begun to explore how EU member states meet the challenge of multilevel governance, that is, the participation of all levels of the national executive in the decision-shaping and decision-making in EU institutions (e.g., Kassim et al., 2000). On the other hand, the increasing globalization of markets and environmental and security concerns have led to the establishment of global governance structures in which the chief executives of the most important 8 (G8) or 20 (G20) states participate (Hajnal, 2007). If anything, this has contributed to a further concentration of power at the top of national governments.

All of the above is about structures and processes. Beginning with the behavioral revolution, research has also focused on people in executive government. Many studies in the elite research tradition compiled and analyzed data on their demographics, social background, and career patterns (e.g., Blondel, 1980; Blondel and Thiébault, 1991; Krook and O'Brian, 2010). While certainly valuable to demonstrate cross-national differences and the impact of social and political change of great magnitude, it has remained doubtful that inferences can be made from these data on the behavior of incumbents. The gender issue might be a possible but still an empirically underresearched exception.

Executive Government Capacity, Output, and Performance

Basic constitutional choices, specific institutional constraints, the partisan makeup of government, and executive control over the legislature determine the policy-making capacity of government to a large degree.

Executive governments in presidential systems have traditionally been considered structurally weak under conditions of 'divided government' (i.e., when the legislature or individual chambers and the presidency are held by representatives of different parties). Such division of power is implicit in the design of presidentialism and intended to cause interinstitutional cooperation and partisan policy-moderation. In cases of ideological or severe policy conflict, however, cooperation is likely to fail and policy stalemate or deadlock to result (Binder, 2003). While presidential powers typically ensure that the country's foreign and military policy is not too greatly affected in such instances, other government business may suffer severely. Repeated shutdowns of most of the US government services in recent years resulting from the failure to pass budgets have angered citizens and sent unwelcome signals to the markets.

Divided government can also occur in semi-presidential systems when the presidential and the parliamentary elections result in different majorities. Typically, such incongruence is less consequential, as the prime minister/cabinet/parliamentary majority bloc clearly outweighs the president/parliamentary minority one (Elgie, 1999; Elgie and Moestrup, 2008). In parliamentary systems, single-party majority cabinets are the structurally strong governments, and coalition and minority cabinets the structurally weak ones. In all regime types, governing becomes more challenging when the government or its legislative support base suffers from great internal policy distance or internally divided parties (factionalized, ideologically incohesive).

Government capacity critically hinges on the quality of the incumbents and the visions and skills of the individuals. While suitable candidates are not always available, selection mechanisms – institutional and intraparty mechanisms – can privilege some individual qualities over others (Heclo, 1973).

It is also important to consider cabinet stability in this context. It is generally accepted that instable government is weak. Depending on the regime form and the research perspective, the theoretical concept of 'government stability' has been defined differently. Most definitions focus on government duration. Here parliamentary systems offer the greatest range of measurement options, as different criteria can define a government: formal acts (official in and out dates), the identity of the prime minister, elections, party composition, and even the cabinet's majority status (majority, 50%, minority). Each change is potentially important. The standard definition of cabinet includes elections, party composition, and identity of the prime minister, but more or less comprehensive definitions may suite a particular research purpose better. In multiparty presidential systems, the same set of indicators can be applied (Shin, 2013). As these indicators are unambiguous, smoothly translate into quantitative data, and are relatively easily collectable over time and space, government stability has become a well-researched topic (Warwick, 1994; Saalfeld, 2013; Schleiter and Morgan-Jones, 2009).

The other perspective on government stability is stability in executive leadership that focuses on either the one specific office (president, prime minister, or whatever title is used) (Bienen and van de Walle, 1991) or the group of top executives (the cabinet members) (Huber and Martinez-Gallardo, 2008; Fischer et al., 2012). This research shows that in parliamentary systems cabinet membership stability is only loosely related to the first type of cabinet stability. More traditional political scientists and game theorists alike have related ministerial instability to gains of the bureaucracy in terms of autonomy (Rose, 1976; Huber and Lupia, 2001). At the same time, each change potentially delays government business.

Many different mechanisms are behind change in cabinet membership and portfolio allocation, including changes in the party composition; shifts of power between the cabinet parties; death or illness of cabinet members; shifts in intraparty power; the firing, hiring, promotion, and demotion of individual ministers according to their performance or public standing; and symbolic action by the prime minister to regain momentum. Such a vast area of conceptually different and often hard-to-measure variables calls for country expertise. So far, this research tradition is often rooted in national case studies,

which do not, of course, preclude the use of quantitative data and statistical methods (Indridason and Kam, 2008; Dowding and Dumont, 2009; Berlinski et al., 2012).

Political observers often employ the term 'stable government' in yet another sense: its firm support, internal cohesion, and capability of making decisions and forcefully interacting with its environment. The presence of variables that explain cabinet instability in terms of turnover indicates that statistically, the government is more likely to fall than those without these characteristics. Crisis periods typically precede the fall of cabinets, internal conflict, and stalemate in decision-making. Given that considerably more such crises are to be expected than cabinet falls (as brinkmanship may succeed), structurally weak governments are likely to be unstable in this second sense of the word.

Yet, not too much should be inferred from the latter for actual performance of these governments. Government builders may have established governance mechanisms to at least partly compensate for structural weaknesses. A desideratum in research is therefore an attempt to conceptually and empirically come to grips with this commonly held idea of stable government. One way to address it would be the systematic analysis of nonterminal cabinet crises.

Turning from executive government's performance in terms of survival and stability to output and outcome performance, we need to keep in mind that executive governments are typically the most powerful political actors within states and exercise much and often critical influence on decisions that are important for the fate of nations. These include going to war or making peace and introducing major domestic reforms via legislative programs and devoting public resources to tasks such as education and welfare. Therefore, the performance of executive government is both politically and substantively important.

Actual government behavior manifests itself in individual policy measures, more complex reform packages, the overall legislative program, and budget allocations. International organizations such as the OECD or the EU provide many relevant indicators, most of which relate to country performance. Direct measures of government outputs are rare and mostly generated by individual researchers. While tailor-made for their specific purpose, they are often quite limited in their scope, geographic breadth, and the time covered and therefore only slightly useful for to studying other research questions and building time-series data sources for long-term accumulation of knowledge.

Given the unique position of executive government to exert influence on public policy and the frequent credit claims by incumbents for actual outcomes, researchers also consider the state of the world and how it has changed under a particular government when measuring its performance. Indicators include the classic economic ones (unemployment, economic growth, and inflation rates) and many others relating to all dimensions of human life (e.g., health, education, environmental quality, crime, access to means of communication, etc.). Citizens make similar comparisons, and survey researchers routinely ask about how their respondents' or the country has fared compared with the immediate past. Yet, outcomes such as country performance are influenced by a multitude of time-varying factors other than government policy and thus need to be considered in international comparison. One particular line of government performance evaluation is to measure it against the yardstick of the pledges that political actors made when campaigning for election to executive office. Most of this research after the pioneering study of Royed (1996) has been limited to single countries and a few cabinets, but attempts are under way to make this research comparative (Thomson et al., 2012). A final perspective on the performance of executive government is evaluative at a more abstract level based on survey data of government popularity, approval of the chief executive, trust in government, and, in a historical perspective, lasting reputation.

According to the outcome of legitimacy perspective, a system's legitimacy rests primarily on its achievements rather than the process it employs in producing those outcomes (Scharpf, 1999; Majone, 2006). In this perspective, executive government action remains crucial for system legitimacy.

The attractiveness of executive office on the one hand and the relevance of performance to the electorate on the other are the key mechanisms to tie public policy to the will of the people and hence to ensure democracy in substantive terms. Assuming myopic voters, governments therefore may try to manipulate the business cycle to make sure that the state of the world is good when voters are called or to time their expenditure and taxation policies according to electoral convenience rather than economic needs (Mueller, 2003). While it seems that globalization has largely removed the first of these strategies from the arsenals of most governments, the second one is a remaining concern.

The peril of entrusting one institution and a set of individuals with a great amount of factual power lies in its abuse. Such concerns have traditionally been at the heart of constitutional design. Yet, constitutional constraints and accountability mechanisms do not always work sufficiently. Sadly, many individuals in executive office fall prey to temptations that the office provides, and almost no government is fully immune against such fallibility. Executive government members thus may exploit their office for private or political group advantage by corruption and political patronage or use executive powers to cover up such misbehavior. They may also pervert political competition by *de facto* or formally changing the rules of the game. Such dismal behavior has been diagnosed as a major cause of economic underperformance and failure in societal development (as measured by the Human Development Index). This has given rise to increased attention to corruption, political patronage, and – contrarily – good governance in recent years (Rothstein, 2011).

In the worst case, countries characterized by executive power abuse find themselves on a slippery road to a nondemocratic regime. Such cases abound in the less wealthy world regions with countries such as Zimbabwe (under Robert Mugabe) or Venezuela (under Hugo Chavez) as relevant (though not equivalent) cases. Similar tendencies have been recorded even for European states such as Italy (under Silvio Berlusconi) and Hungary (under Viktor Orbán). The fear of government that has driven classic constitutional thinking thus has not lost any of its relevance today. How to enable the government to carry out its tasks and at the same time to keep it accountable – Madison's question – remains the key issue it has ever been in the history of democracy.

Expectancy-Value-Cost Model of Motivation

Abstract

Expectancy-Value models recognize the important role of two components in promoting overall motivation: having an *expectancy* of being successful in a task and having a *value* for engaging in the task. In this article, we highlight the additional role that the *cost* of engaging in an activity plays in influencing motivation and propose a revised Expectancy-Value-Cost model of motivation. Because cost has been less researched and written about, we pay particular attention to its past, present, and future role in an overall model of motivation.

Although numerous theories of motivation have been proposed over the past few decades, Expectancy-Value models of motivation stand out for their ability to synthesize multiple theoretical perspectives, capture the key components of what motivates an individual, and explain a wide range of achievement-related behaviors. In this article, we review the contemporary perspective of Expectancy-Value models used in education.

As the name suggests, Expectancy-Value models have centered on the importance of two components in promoting overall motivation: having an *expectancy* of being successful in a task and having a *value* for engaging in the task. In addition, as indicated by the title of this article, we propose promoting a third component into the overall name of the model to highlight the additional role that the *cost* of engaging in an activity plays in influencing motivation. Although cost is theorized to be a subcomponent in prior Expectancy-Value models, it has been largely ignored in the past empirical work (Wigfield and Cambria, 2010). Fortunately, cost as a factor has reemerged with recent research demonstrating its importance in capturing motivational dynamics that complement expectancy and value components.

For example, consider the following three students enrolled in a calculus course. Math is a challenging subject for Rory, but by putting in extra effort and adopting the appropriate study strategies he has been able to perform well in prior coursework. However, he finally met his match with calculus. Even with additional effort, he is unable to understand the material. As a result, he lacks confidence that he will do well, and his motivation for calculus has decreased. In contrast, math is an easy subject for Jeff. He has always scored at the top of his class and continues to do well in calculus. But this year, his motivation also has substantially decreased. Jeff struggles to see the utility of learning calculus and how he will use it in the future. Finally, there is Jessica, who excels in math and finds it to be one of her favorite courses. She is also interested in several science careers that use calculus. However, due to an ambitious academic and extracurricular schedule, she is struggling to find enough time to complete her schoolwork. In particular, her grades in math have suffered. She knows she could do it; she just cannot find the time. Now, she too admits her motivation for math is not what it used to be.

Each student faces a unique motivational challenge, reflecting one of the expectancy, value, and cost components. In Rory's case, he lacks the confidence (i.e., expectancy) that he can successfully learn calculus. In Jeff's case, he fails to see a reason or purpose (i.e., value) for learning calculus. However, Jessica's challenge is different. She possesses expectancy and value for math, but there are other barriers in her way (i.e., costs) that are thwarting her from being able to invest the time and energy to be successful. Thus for a comprehensive model of motivation, we propose including all three in the revised Expectancy-Value-Cost model.

Overview of Expectancy-Value Models

For more than 30 years, Eccles and her colleagues (Eccles et al., 1983; Wigfield and Eccles, 2000) have championed a contemporary version of Expectancy-Value models to better understand students' choices, persistence, and performance in education. This work grew out of earlier theoretical models of Expectancy-Value motivation (e.g., Atkinson, 1957; Lewin et al., 1944). Expectancy-Value frameworks also have been developed in other fields, such as Vroom's (1964) Valence-Instrumentality-Expectancy model for work settings, but are beyond the scope of this article focused on education.

There are three defining features of Eccles et al.'s contemporary version of the Expectancy-Value model: it is psychological, developmental, and integrative. First, in terms of being psychological, Expectancy-Value models are rooted in an individual's subjective beliefs. Eccles et al. (1983) stressed, "the model itself is built on the assumption that is not reality itself (i.e., past success or failures) that most directly determines children's expectancies, values, and behaviors but rather the interpretation of that reality" (p. 79). In particular, to be optimally motivated, Eccles et al. (1998) argued that a student has to answer "yes" to two fundamental questions: "Can I do the task?" and "Do I want to do the task?" The first question reflects a belief in having an expectancy to do a task, and the second reflects a belief in having a value or reason to do the activity. To truly understand a student's academic choices and behaviors, Eccles (2006) stressed the importance of needing to understand what a student is 'psychologically thinking.'

Second, in terms of being developmental, the model asserts that expectancy and value are shaped over time by individual and contextual factors (see Eccles et al., 1983, 1998 for reviews). These include personal and family demographics (e.g., gender, culture, and socioeconomic status), past experiences of success and failure, an individual's goals and self-concept, and the influence of different socializing agents (e.g., parents, teachers, peers, and schools). Expectancy and value beliefs then are hypothesized to influence the specific academic choices, persistence, and performance of a student in school. For example, Eccles originally developed her version of the Expectancy-Value model in the late 1970s and early 1980s to understand why girls were less likely to persist in taking higher-level math courses, even though they performed similarly to boys in early math courses. The bulk of research supporting this model has focused on large-scale, correlational studies where students self-report their expectancies and values and then are tracked over time to investigate achievement-related outcomes. Although expectancies and values are positively correlated with a wide range of adaptive achievement outcomes, a unique pattern emerges when both are tested simultaneously. Expectancy is more predictive of performance outcomes, and value is more predictive of continued interest and future course taking outcomes (Eccles et al., 1983; Wigfield and Eccles, 2000). Despite the clear associations between expectancy and value and important educational outcomes, the growing body of developmental work also reveals an overall negative picture of student motivation. Students' expectancies and values typically decline as they progress through school (Jacobs et al., 2002).

Third, in terms of being integrative, the Eccles et al.'s model synthesizes multiple perspectives. In her earliest writing (see Parsons, 1980), Eccles observed how the adoption of different theoretical perspectives led researchers to focus on distinct subsets of the possible factors affecting achievement motivation with no clear way to link or integrate discrepant findings. Thus, she set out to develop a comprehensive motivational framework that integrated different perspectives to better explain students' academic choices, persistence, and performance. She also emphasized the importance of identifying motivational factors that were modifiable, which in turn could be used to design interventions to enhance student motivation. This led her to an Expectancy-Value framework and the components of expectancy, value, and cost, which we elaborate on in separate sections below.

The Expectancy Component

As noted above, the question "Can I do the task?" parsimoniously captures the essence of the expectancy component (Eccles et al., 1998). When students believe that they can do something, they are more likely to engage in that behavior. Initially, Eccles and her colleagues argued that expectancy beliefs were multifaceted and that there was merit in distinguishing between two types of expectancies: *ability beliefs* that comprised someone's current/immediate beliefs about being able to complete a task and *expectancy beliefs* that reflect being able to do the task in the future. However, even though this clear, theoretical distinction is possible, empirical studies of these two subcomponents reveal that they are highly correlated and 'empirically indistinguishable' (Eccles and Wigfield, 1995). As a result, most investigations combine measures of ability and expectancy beliefs into a general expectancy scale. Although ability/expectancy beliefs fail to separate *within* a specific academic or nonacademic domain, students do hold different expectancy beliefs *across* different subjects in school (e.g., that they are better in math than English).

From the outset, Eccles et al. (1983) highlighted the close connection between expectancy and other constructs linked to students' beliefs about being able to complete a task, such as self-concept of ability, task difficulty, locus of control, and attributions. In subsequent writing, Eccles and Wigfield (1995, 2002) highlighted how expectancy was related to other theoretical perspectives such as Self-Efficacy Theory (Bandura, 1986), Self-Worth Theory (Covington, 1992), and Attribution Theory (Weiner, 1979). Similarly, we find it easy to link expectancy to more recently proposed motivational constructs, such as academic mindsets (Dweck, 2006). Thus, the expectancy component of Expectancy-Value models offers an overarching, umbrella construct that can capture and integrate a wide range of theoretical perspectives focused on the importance of believing that one can accomplish a task (see Eccles and Wigfield, 2002; Wigfield and Eccles, 2000 for reviews).

The Value Component

As noted above, the question "Do I want to do the task?" was offered as a parsimonious way to capture the essence of the value component (Eccles et al., 1998). When students hold the belief that they value something, they are more likely to engage in that behavior. Building on the work of earlier value researchers (e.g., Battle, 1966; Crandall et al., 1962; Feather, 1982; Rokeach, 1980), Eccles and her colleagues proposed many reasons why a task would hold value for an individual.

The first is *intrinsic* or *interest* value that reflects the inherent enjoyment an individual experiences from engaging in the task for its own sake. The second is *utility* value that reflects the usefulness of a task in helping achieve other short-term or long-term goals. In some of their work, Eccles and her colleagues labeled this extrinsic utility to emphasize engaging in a task as a means for achieving another end. The third is *attainment* value that reflects that the task affirms a valued aspect of an individual's identity and meets a need that is important to an individual. In particular, attainment value represented a way for Eccles and her colleagues to capture a wide-array of additional values suggested by other researchers (e.g., Rokeach, 1980), without assessing each of these additional values separately (e.g., relatedness value, competence value, and esteem value).

In contrast to the first three subcomponents of value that reflect positive reasons to want to engage in an activity, Eccles et al. (1983) proposed a fourth value labeled *cost*. Eccles et al. suggested that the overall value of a task can be negatively impacted by the perceived costs associated with performing the task. Initially, three types of cost were hypothesized: the amount of effort needed to be successful in the task, the time lost to engage in other valued activities, and negative

psychological states resulting from struggle or failure in the task. The first two types of cost were hypothesized as costs of success (e.g., having to give up time and energy for a task or having to give up doing other valued activities), whereas the third was linked to costs of failure (e.g., embarrassment or anxiety). It was predicted that the choice to want to do an activity would entail a cost/benefit analysis. As the level of cost increases, the overall value of the activity should decrease.

Thus, four different subcomponents of value were proposed to influence an individual's overall value of an activity: intrinsic value, utility value, attainment value, and cost. Eccles and Wigfield (1995) wrote "the first three [sub] components are best thought of as attracting characteristics that affect the positive valence of the task … cost, in contrast, is best thought of as those factors … that affect the negative valence of the activity" (p. 216). However, the work of Eccles and her colleagues remains largely silent on how to effectively measure cost or how researchers should weight the positive and negative subcomponents of value into an overall measure. Instead, their work concentrates on evaluating the positive subcomponents. Empirical work testing the factor structure supports the separation of the three positive types of value for students in fifth through twelfth grade (Eccles and Wigfield, 1995). However, in younger students, positive value beliefs only separate reliably into one or two factors (Eccles et al., 1993; Wigfield and Eccles, 1992).

Finally, like expectancy, the value component in the Eccles et al.'s model also offers an overarching, umbrella construct that captures and integrates a wide range of theoretical perspectives focused on the importance of wanting to engage in the task (see Eccles and Wigfield, 2002 for a review). These include Self-Determination Theory (Deci and Ryan, 1985), Interest Theories (Hidi and Renninger, 2006), Intrinsic–Extrinsic Motivation Theories (Sansone and Haraciewicz, 2000), Self-Worth Theory (Covington, 1992), and Achievement Goal Theories (Ames, 1992).

The Cost Component

In contrast to the extensive body of work on expectancy and the positively valenced value components, there has been far less empirical work on cost. To honor its theoretical placement in Eccles et al.'s model, an initial discussion of cost was included above in the section of the value component. However, as promised, we review here the past, present, and future role of cost in Expectancy-Value models. Importantly, we consider whether cost is worthy of being promoted from a subcomponent of value as in past theorizing of Expectancy-Value models to a major component that complements expectancy and value components. We will also consider whether an additional overarching question (such as "Can I do the task?" and "Do I want to do the task?") would be beneficial to propose to parsimoniously capture the role of cost.

Past Work

In terms of its past, we first reconsider the theoretical placement of cost in Eccles et al.'s Expectancy-Value model. In their earliest writing, cost was described as an important mediator of value (Eccles et al., 1983). However, in subsequent writing, cost was promoted to one of four subcomponents of value (along with intrinsic, utility, and attainment) that would be weighted in a cost/benefit analysis to determine one's overall value. This type of relationship implies that cost is better conceived of as a moderator variable of value instead. In a moderator relationship, the effect of one variable on an outcome depends on knowing the level of another variable. In other words, the overall effect of value on promoting motivation depends on knowing whether or not someone experiences high or low cost. Thus, incorporating cost into our Expectancy-Value models is critical to fully capturing the motivational dynamics of what attracts or detracts us from engaging in an activity.

Beyond influencing value, it is possible to deduce additional connections on how cost negatively affects expectancy from Eccles and her colleagues' writing. This suggests that cost has a more prominent role than previously indicated. For example, Eccles et al. (1983) linked expectancy beliefs to two variables that we believe serve as proxies for two of the three hypothesized dimensions of cost. First, with regard to cost resulting from the amount of effort required for an activity, Eccles et al. discussed task difficulty perceptions as one of the two main contributors to expectancy beliefs, with the other being an individual's ability beliefs in that domain. When developing initial measures, Eccles and colleagues measured different dimensions of task difficulty and ability beliefs suggesting that both would interact to predict an individual's overall expectancy. Ability beliefs were predicted to positively impact expectancy, while task difficulty was predicted to negatively impact expectancy. In particular, one of the task difficulty dimensions assessed the effort required by the activity, which seems clearly related to costs due to the amount of effort required by the activity.

If task difficulty is reevaluated in this light, past research by Eccles and her colleagues offers evidence how cost may fit into a modified Expectancy-Value-Cost framework. In their most rigorous test of the factor structure of the core components of their model, Eccles and Wigfield (1995) found that their analyses supported a structure of three task values (interest, importance, and utility), one combined ability/expectancy factor, and two task difficulty factors (perceptions of difficulty and perceptions of effort required to do well). Although no explicit measure of cost was included, if we use task difficulty as a proxy for cost (especially items assessing the perceptions of effort required to do well), we have support that cost separates into its own factor rather than loading negatively on either of the other value or expectancy factors. Furthermore, while value and expectancy scales were positively correlated with each other, they were all negatively related to the task difficulty scales. These findings are in line with predictions of how cost should be negatively related to both value and expectancy. Consequently, the work of Eccles and colleagues may not be so silent on offering empirical evidence for the distinction of a unique cost component that is related to both expectancy and value components.

Second, we also found Eccles and her colleagues linking expectancy to costs occurring from negative psychological

consequences. While reviewing expectancy beliefs, Eccles et al. (1983) highlighted a series of studies debating the relationship between expectancy and the negative psychological experience of math anxiety. Fennema and Sherman (1977) argued that math anxiety and expectancy were psychologically equivalent and simply the inverse of each other. In contrast, Meece (1980) argued instead that math anxiety resulted from a combination of low expectancy for success coupled with high psychological cost from a fear of failing. To test these competing ideas, Wigfield and Meece (1988) developed a measure designed to assess affective and cognitive dimensions of math anxiety while being careful to avoid item overlap that would artificially inflate the relationship between anxiety and expectancy. They found that the affective dimension of math anxiety shared moderate to strong negative correlations to expectancy and value, while the cognitive dimension had weak relationships. Moreover, while the affective dimension continued to be more strongly correlated to expectancy than value, it was not as strongly correlated as Fennema and Sherman (1977) suggested. These findings reveal that if math anxiety measures offer a proxy for assessing the negative psychological dimension of cost, we can infer that cost is clearly linked to expectancy.

Furthermore, Wigfield and Meece (1988) included measures of task difficulty, offering an additional test to evaluate how different hypothesized types of costs could be related. The affective anxiety scale was found to share strong, positive correlations with each of the different scales of task difficulty. Interestingly, they suggested that future research should explore the links between math anxiety, performance, and other components of the Expectancy-Value model more fully. They also argued that math anxiety should be considered conceptually distinct from expectancies. In particular, they highlighted the implications that this has for students:

> Our results show that the anxiety that students report represents more than a lack of confidence in math; rather it also centers on negative affective reactions to math. In regard to intervention efforts to alleviate math anxiety, we would suggest that techniques to build anxious students' confidence in their math ability may not be enough to alleviate the strong negative affective reactions to math that they experience. Math anxious students also need training to reduce their fear and dread of math. As has been found in the test anxiety area, intervention efforts focused on both the cognitive and affective components of math anxiety may prove to be the most effective way to reduce its debilitating effects (p. 214).

Thus, identifying cost as a subcomponent of value appears to lack both conceptual and empirical support. Instead, we propose it is time to promote cost to a major component that could be combined and interacted with both expectancy and value components to determine when someone is optimally motivated. Of course, this quickly becomes an empirical question. Although initial attempts were made to include cost from the outset of their work (Parsons, 1980), explicit measures of cost and analyses incorporating cost were not fully developed. Without well-developed and agreed upon measures of cost, we are unable to test models that evaluate the merits of keeping expectancy, value, and cost components separate, and how these three components relate to each other and to student outcomes.

Present Work

Fortunately, interest in studying cost is changing in the present. First, researchers are adopting qualitative approaches that support the inclusion of cost constructs in addition to expectancy and value constructs to more fully capture motivational dynamics. For example, Watkinson et al. (2005) interviewed elementary-aged students to determine the reasons why children chose to participate in or avoid different activities during recess. When discussing reasons that made them avoid participating, children described psychological costs (e.g., being teased) as well as physical costs (e.g., being uncomfortable) in addition to identifying reasons linked to expectancy and value components. Similarly, Xiang et al. (2006) asked children why they liked or disliked participating in particular programs in gym class (e.g., a running unit). Again, a major portion of comments for why students disliked particular programs focused on perceived costs. Finally, Chen and Liu (2009) used qualitative approaches as part of a mixed method study of student motivation to participate in university physical education classes. They measured expectancy and values quantitatively using modified items from Eccles and Wigfield (1995), but due to the lack of a validated scale for cost, they interviewed students to obtain qualitative data on perceived cost. Students offered numerous cost explanations for choosing to stop taking physical education, such as having a heavy workload and other pressing demands on their time.

In addition to qualitative investigations highlighting the importance of cost components, a number of researchers are beginning to measure cost quantitatively. Chiang et al. (2011) surveyed elementary students' about their expectancy, value, and cost beliefs and their willingness to participate in physical activity. They used existing items by Eccles and her colleagues to measure expectancy and value, but added three new items to assess cost (with one item for each of the three subtypes of cost proposed by Eccles et al., 1983). Factor analyses revealed cost loaded on a separate factor from a combined expectancy/value factor. When predicting levels of physical activity, students reporting higher costs were less likely to be active, whereas students reporting higher expectancy/values were more likely to be active.

Returning to a more traditional academic domain, Luttrell et al. (2010) reported the development of a new assessment inventory to measure interest value, utility value, attainment value, and personal cost for math. The cost items focused on two of the three types of cost proposed by Eccles et al. (1983): the amount of effort required by the activity and negative psychological consequences. Interestingly, many of the cost items were similar to the math anxiety items reported in Wigfield and Meece (1988). Factor analysis supported a four-factor solution. Cost was found to be negatively correlated to all three value scales, whereas the three value scales were positively correlated to each other. In addition, students who took three or more college courses rated math less costly than those who took zero, one, or two courses.

Conley (2012) included two new cost items in a large scale study to determine the most common motivation profiles for math students in middle school. Her new items focused on only one type of cost: the loss of engaging in valued alternatives. Again, cost formed a unique factor and was negatively correlated with expectancy, intrinsic value, utility value, and attainment value. Cluster analyses also revealed that cost played a critical role in discriminating more and less adaptive motivational profiles. Then on a measurement note, Conley offered a warning that totaling value and cost scales into an overall value index could mask important differences in motivational profiles of students. For example, the cluster of students who reported lower interest and lower cost would have the same overall value index as another cluster of students who had higher interest and higher cost, even though their profiles were quite different.

Finally, in a large-scale study of both mathematics and English, Trautwein et al. (2012) evaluated items designed to assess cost, expectancy, intrinsic value, utility value, and attainment value. Their cost measure included one item focused on the amount of effort necessary for the class and one item focused on the loss of engaging in valued alternatives. For both math and English, factor analyses revealed that cost and the three value factors supported a four-factor structure. Furthermore, cost was negatively correlated to all three values, and was the most negatively correlated to expectancy. Finally, analyses indicated that students' expectancy, value, and cost beliefs differed by academic domain (e.g., that students perceived different levels of cost for math than English).

In our own research program, we have also been active in reconsidering the role of cost in Expectancy-Value frameworks, and how to approach measuring it. We also adopted qualitative and quantitative approaches to inform our understanding. As part her master's thesis, Flake (2012) conducted a comprehensive literature review of the conceptualization and measurement of cost to determine the core dimensions of cost. Then she followed an in-depth scale development process that included additional qualitative data collection with students. Her goals were to reevaluate the proposed dimensions found in the literature, propose a new pool of items to assess each of the dimensions that emerge, and utilize outside experts to review items for their ability to assess each dimension. A number of major findings emerged that now shape our views about cost.

First, a review of the educational psychology literature consistently revealed three dimensions of cost that Eccles et al. (1983) proposed from the outset of their work: (1) the amount of effort required to be successful in the task, (2) the loss of being able to engage in other valued activities, and (3) negative psychological states resulting from struggle or failure in the task. However, review of the psychological literature outside of education (specifically in behavioral economics) suggested the merits of adding another dimension of cost. Having decreased motivation to engage in a task may result not only from the amount of effort required by the activity itself, but also from the amount of effort that an individual has to exert on other activities that he or she is engaged in. As a result, Flake proposed adding two types of effort costs: the amount of effort required by the task itself (i.e., effort-related cost) and the amount of effort required by other tasks (i.e., effort-unrelated cost). Most university faculty who try to pursue their research know these two types of effort costs all too well when they consider how to find enough time to dedicate to research (effort-related costs) when they have teaching and service responsibilities to juggle as well (effort-unrelated costs). Similarly, in our opening example of the three students taking a calculus class, we initially diagnosed Jessica's motivational problem as cost. But now if we extended the diagnosis to a particular type of cost, the original three dimensions of cost do not directly capture her motivational problem. Instead, it stems from taking on too many high-demanding classes and extracurricular activities that are thwarting her ability to put more time and energy into calculus (i.e., she is experiencing effort-unrelated cost).

In addition to proposing new dimensions of cost, a second major finding from Flake's (2012) work is how items need to be written to best capture cost. A defining feature of Expectancy-Value models rests in an individual's subjective appraisal of the core components. In her qualitative study, Flake asked students to describe features of their most and least motivating classes in college. Interestingly, students reported effort-related costs (e.g., the class was challenging) in both their most and least motivating classes. However, their appraisals were quite different. In their most motivating class, expending additional effort was perceived positively; but in their least motivating class, it was clearly perceived negatively. This informed how to best approach creating a pool of items to measure cost. For example, as we suggested above, task difficulty measures from prior research could serve as a proxy for effort-related cost. One possible way to assess task difficulty could be to measure how challenging a course is (e.g., 'This class is challenging.'). However, challenge can actually increase a student's value because it pushes a student to grow increasing his or her competence. Instead, we recommend writing cost items that capture a negative appraisal from the outset (e.g., 'This class is *too* challenging.'). To agree that a class is *too* challenging suggests it has surpassed a critical threshold and that it is now overwhelming and is perceived to have cost. Measuring cost objectively as the amount of effort or task difficulty alone is not enough. To be perceived as cost, it must be perceived negatively by the respondent.

In terms of quantitative approaches, we are currently involved in a grant project funded by the National Science Foundation to develop a rapid measure of expectancy, value, and cost that can be easily adapted and used across a wide age range and academic domains. We also are testing the measure to see the utility of measuring expectancy, value, and cost at different levels of specificity. For example, we have assessed expectancy, value, and cost at the level of a specific academic task (e.g., for a science unit on carbon), at the level of a specific class (e.g., biology), and at the level of academic semester (e.g., for your coursework this semester). We have three major preliminary findings to report (Flake et al., 2011; Getty et al., 2013; Lazowski et al., 2012). First, factor analyses strongly support the separation of expectancy, value, and cost components into three different scales. Second, expectancy and value are positively related, but in turn are both negatively related to cost. Third, expectancy, value, and cost provide unique

predictive validity on important educational outcomes when tested simultaneously in regression or path models. Expectancy is the strongest, positive predictor of performance outcomes (e.g., test score for a science unit or final grade in an academic class), but is unrelated to interest outcomes (e.g., continued interest in studying that topic or pursuing a career in that area). In contrast, value is the strongest predictor of interest outcomes, but is unrelated to performance outcomes. Cost, however, is a negative predictor of *both* interest and performance outcomes and improves our ability to predict both. We also initiated a longitudinal study to track middle school students' expectancy, value, and cost for their math coursework. Our initial wave of results found small downward trajectories for fifth through seventh grade on expectancy and value, and small upward trajectories for cost. However, large drops in expectancy and value and large increases in cost occur by the time students end eighth grade.

In sum, current qualitative research showcases the value of adding cost into our overall motivation framework, especially to better understand the barriers when individuals are unmotivated. In addition, more researchers are designing and incorporating new measures of cost in quantitative studies. This work is consistently revealing that cost separates into its own factor and is empirically distinguishable from expectancy and value factors.

The Future

With renewed energy and a growing body of researchers now investigating cost, we expect many advances to occur over the next few years. With this work, a number of key questions will need to be addressed as future research unfolds. First, we need to resolve how cost is conceptualized and measured. For example, in our work, we proposed adding at least one additional dimension of cost above and beyond the original theorizing of Eccles et al. (1983), but one key question is, are there other dimensions worthy of consideration? Furthermore, because multiple dimensions may contribute to cost, researchers need to pay particular attention to how a measure is designed and compared with other research. As evidenced by most of the cost work cited above, researchers assessed only one or two of the potential dimensions in a given study. Also, it is not clear how cost dimensions will function alone by themselves or in conjunction with each other. Perhaps the experience of one type of cost could be enough to deter a student from being motivated, thus creating measures of multiple dimensions and totaling them into a total score might be misleading and mask important effects.

Second, we need to consider how cost is tested in conjunction with expectancy and value. We propose that it is time to promote cost to a major component of Expectancy-Value models, so that researchers can simultaneously test the independent and joint effects of expectancy, value, and cost together. In other words, cost needs to enter our models in a way that allows a test of both its independent, additive effect as well as its potential moderator effect that can alter how motivated individuals are depending on their level of expectancy and/or value. This presents a major paradigm shift from early theorizing that explicitly suggested that cost was a mediator or moderator that led to an overall value belief. In addition, although much of the existing work on Expectancy-Value by Eccles and her colleagues had downplayed the interactive or moderating role of expectancy and value, recent methodological developments in modeling interaction terms have emerged to offer more powerful tests, and have found support that the interaction between expectancy and value adds additional variance in explaining outcomes (e.g., see Trautwein et al., 2012). Now it is time to extend these tests to look at interactions involving cost as well.

Final Thoughts

In this article, we have reviewed the current state of Expectancy-Value models in education, and the importance of developing a student's expectancy that he or she can do the task ("Can I do the task?") and a student's value that he or she wants to do the task ("Do I want to do the task?"). However, in addition to having students respond yes to both of these questions to be optimally motivated, a student needs to be free of costs in order to demonstrate motivated behavior.

In our revised Expectancy-Value-Cost model, cost is a distinct component, alongside expectancy and value, which determines motivated behavior. We argued that cost is multidimensional with at least four subcomponents: effort related to the task, effort unrelated to the task, loss of valued alternatives, and negative psychological experiences. In addition, the effort and resources required for an activity are costly only when they are perceived to be too much by a student.

Thus, we would like to close with a new third question that captures the importance of being free of costs that can prevent us from being motivated. Specifically, to be optimally motivated, we need to ensure an individual also says yes to the question: "Am I free of barriers that prevent me from investing my time, energy, and resources into the activity?" As our opening example of students suggests, a student could clearly hold a belief that "Yes, I can do a task" and "Yes, I value the task," but still remains unmotivated because the student's final answer is "No, I have barriers preventing me from engaging in the task." If we only ask two of these three questions, the scope of our models to predict and understand motivation will be limited.

Eccles and Wigfield (1995) highlighted in their article most extensively evaluating the measures of their model that "over time, there has been an evolution in the conceptualization of constructs linked to expectancy for success and task value, as well as a refinement in the components of each construct" (p. 217). We predict continued evolution once again, as renewed energy is focused on cost and on the question of how the components of expectancy, value, and cost work together to impact motivation.

Abstract

Expectations are central to the determination of macroeconomic variables. Since the 1970s, 'adaptive expectations' have been replaced by 'rational expectations' (RE), with expectations modeled as optimal forecasts. Some economic models exhibit multiple RE, giving an independent role for expectations. The learning approach goes beyond RE to ask whether and how agents might coordinate on RE. Adaptive learning theories can also generate novel learning dynamics. Survey data, estimates of expectations based on market data, and experimental results are increasingly studied.

'Expectations' in economics refers to the forecasts or views that decision-makers hold about future prices, sales, incomes, taxes, or other key variables. The importance of expectations is due to their often substantial impact on the current choices of firms and households, and hence on current prices and the overall level of economic activity. For example, present value calculations in investment decisions are conditional on expected future prices and sales. Equity prices, interest rates, and exchange rates all clearly depend on expected future prices.

Modern economic theory recognizes that the central difference between economics and natural sciences lies in the forward-looking decisions made by economic agents. Therefore, expectations are a basic building block of economic theories. A central aspect of economic theories is that expectations influence the time path of the economy, and conversely one might reasonably hypothesize that the time path influences expectations. The rational expectations (RE) hypothesis, which portrays expectations as an equilibrium in this two-sided relationship, has been the standard methodology for modeling expectations for several decades. Recently, new models and theories have sought to extend and improve the RE approach.

Expectations in the History of Thought

Systematic economic analyses in which expectations play a major role began in the nineteenth century. Alfred Marshall is credited with the notion of 'static expectations' of prices. The 'cobweb' model of a market with a production lag was one of the first formal models with expectations in the 1930s. In the same decade, the temporary equilibrium approach explicitly introduced expectations of future prices influencing current demands and supplies. John Muth was the first to formulate the notion of RE in 1961 (reprinted in Lucas and Sargent, 1981).

In macroeconomic contexts, the importance of the state of long-term expectations of prospective yields for investment and asset prices was emphasized by John Maynard Keynes (1936) in his General Theory. Keynes stressed the central role of expectations for the determination of output and employment, but did not have an explicit model of how expectations are formed. He even sometimes suggested that attempting to forecast very distant future events can virtually overwhelm rational calculation.

In the 1950s and 1960s formal models of expectations were incorporated into almost every area of macroeconomics, including consumption, investment, money demand, and inflation, using adaptive expectations (AE) or related schemes. AE were formally introduced in the 1950s by Phillip Cagan, Milton Friedman, and Marc Nerlove.

RE made the decisive appearance in macroeconomics in the work of Robert E. Lucas Jr. and Thomas J. Sargent in the beginning of 1970s. Many of the key contributions are collected in Lucas and Sargent (1981) and Lucas (1981). The RE hypothesis became widely used in the 1970s and 1980s and it is currently the benchmark paradigm in both micro- and macroeconomics. Most recently, models of *learning behavior* and related research have gone beyond RE by incorporating explicit theories of data collection and forecasting into economic models.

In this article we review models of expectation formation, with an emphasis on RE and more recent developments. RE modeling is the subject of many books, see e.g., Sargent (1987) and Farmer (1999). Evans and Honkapohja (2001) is a treatise on the learning approach.

Traditional Models

We illustrate the modeling of expectations with some well-known simple models. The first example is the cobweb model of a single competitive market with a time lag in production. Demand d_t is assumed to depend negatively on the prevailing market price, while supply s_t depends positively on the expected price, i.e., at time t,

$$d_t = m_I - m_p p_t + v_{1t} \quad \text{and} \quad s_t = r_I + r_p p_t^e + v_{2t}$$

where m_p, $r_p > 0$ and m_I, r_I denote intercepts. Here v_{1t}, v_{2t} are exogenous *iid* (identically and independently distributed) random shocks with mean zero and constant variance. Random shocks of this type are called 'white noise.' The model is illustrated in **Figure 1** in which, for simplicity, we have assumed there are no random shocks, i.e., $v_{1t} = v_{2t} = 0$. Note

 http://dx.doi.org/10.1016/B978-0-08-097086-8.71005-1

Figure 1 Cobweb model.

that expected price and market-clearing price are on the horizontal axis with corresponding quantities supplied and demanded on the vertical axis.

The supply function reflects a 1-period production lag. Supply decisions for period t are made in the previous period $t-1$ and depend on the price p_t^e expected at time $t-1$ given information available. For simplicity, we make the 'representative agent' assumption that all firms have the same expectation. Extensions to heterogeneous expectations have been analyzed in the literature.

We assume that markets clear. The price p_t at t is then obtained by equating s_t and d_t, which gives

$$p_t = \mu + \alpha p_t^e + \eta_t \qquad [1]$$

where $\mu = (m_I - r_I)/m_p$ and $\alpha = -r_p/m_p < 0$. Here $\eta_t = (v_{1t} - v_{2t})/m_p$ so that η_t is white noise.

In Figure 1, in which there are no random shocks, there is a single price $\bar{p}$ that has the property that expectations will be realized: if $p_t^e = \bar{p}$ then $p_t = \bar{p}$. Here $\bar{p}$ is called the 'perfect foresight' price because firms precisely forecast its value. The corresponding quantity produced is $\bar{s}$, and when this quantity is supplied to the market, the corresponding market-clearing price is indeed $p_t = \bar{p}$. If instead $p_t^e \neq \bar{p}$ then the actual price will be different from the one expected. This is illustrated in Figure 1: if $p_t^e = \tilde{p}^e > \bar{p}$ then firms will supply a large quantity $\tilde{s}$ and this will lead the market-clearing price in period t to be $p_t = \tilde{p} < \bar{p} < \tilde{p}^e$.

If random shocks to supply and demand are included then it is not possible to have perfect foresight. The corresponding concept is instead called RE. Under RE firms will make forecast errors, but these errors will be random and unsystematic, as discussed further below.

Note that the cobweb model leading to eqn [1] has negative feedback from expectations to outcomes, since $\alpha < 0$. This is why high expected price in Figure 1 leads to a low actual or realized price. Positive feedback versions of eqn [1] in which $\alpha > 0$, e.g., macroeconomic models based on the 'Lucas supply curve,' are equally important.

Equation [1] is an example of a temporary equilibrium relationship. This illustrates the central role of expectations by showing how the current market-clearing price depends on expected prices. Developments since the 1930s can be seen as different theories of expectations formation, i.e., how to close the model so that it constitutes a fully specified dynamic theory.

Static expectations and AE were the two models of expectations formation most widely used in the early literature. In the cobweb model static expectations take the form $p_t^e = p_{t-1}$. In effect static expectations assume that the most recently observed price is the best predictor of next period's price. Substituting into [1] one obtains $p_t = \mu + \alpha p_{t-1} + \eta_t$. If there are no random shocks this simply becomes $p_t = \mu + \alpha p_{t-1}$. In terms of Figure 1, and moving to the next time period, the expectation at time t of next period's price is given by $p_{t+1}^e = p_t = \tilde{p}$. Moving up to the supply curve, across to the demand curve and down gives the next period's price, which in the case shown will be somewhat higher than $\bar{p}$.

The sequence of prices over time is equivalently given by the dynamic equation $p_t - \bar{p} = \alpha(p_{t-1} - \bar{p})$, where the perfect foresight price is $\bar{p} = (1-\alpha)^{-1}\mu$. It can be seen that (1) if $\alpha < 0$ prices alternate between positive and negative deviations from $\bar{p}$, and (2) prices converge over time to perfect foresight if and only if $|\alpha| < 1$. If $\alpha < -1$ prices follow an explosive cycle that does not converge. Whether the stability condition $|\alpha| < 1$ is satisfied depends on the relative slopes of the demand and supply curves.

When there are random shocks and static expectations the sequence of prices given by $p_t = \mu + \alpha p_{t-1} + \eta_t$ is random and follows a stochastic process known as an autoregressive process of first order. This and related stochastic processes are studied in standard textbooks on time series analysis and econometrics. In the stochastic case the condition $|\alpha| < 1$ determines whether the price converges to a stationary stochastic process centered on $\bar{p}$.

Beginning in the early 1960s the static expectations hypothesis was largely replaced by AE. In the cobweb model this takes the form

$$p_t^e = p_{t-1}^e + \lambda\left(p_{t-1} - p_{t-1}^e\right)$$

where $0 < \lambda < 1$. Under AE expectations partially respond to the most recently observed price: expectation p_t^e is a weighted average of p_{t-1} and the previous expectation p_{t-1}^e, where λ is the weight on p_{t-1}.

AE supplanted static expectations for three reasons. First, it seems plausible that firms would use all past prices, not just the most recent one, in forming expectations. It can be shown that AE can equivalently be written as a distributed lag average of past prices with weights declining geometrically at rate $1-\lambda$ over past data. Second, it is more general than static expectations, which is equivalent to $\lambda = 1$.

Third, AE tends to be more stable than static expectations. In the nonstochastic case AE converges to perfect foresight if and only if $|1 - \lambda(1-\alpha)| < 1$. In the stochastic case with AE it can be shown that both expectations and prices converge to stationary stochastic processes centered on the perfect foresight price provided the last condition is met. Under AE the stability condition is satisfied for a wider range of parameters than under static expectations. For example, if $\lambda = 1/3$ stability holds if $-5 < \alpha < 1$. Below we show that under econometric learning stability holds for all $\alpha < 1$.

AE played a prominent role in macroeconomics in the 1960s and 1970s. For example, inflation expectations were often modeled this way in the analysis of the expectations augmented Phillips curve. Besides AE, other distributed lag formulations were used in the literature to allow for extrapolative or regressive elements.

Rational Expectations

The RE revolution begins with the observation that AE, or any other fixed weight distributed lag formula, may provide poor forecasts in certain contexts and that better forecast rules may be readily available. The optimal forecast method depends on the stochastic process of the variable being forecast and this implies interdependency between the forecasting method and the economic model. On this approach we write

$$p_t^e = E_{t-1}p_t$$

For the cobweb example $E_{t-1}p_t$ denotes the mathematical expectation of p_t conditional on variables observable at time $t-1$ (including past data).

RE is an equilibrium concept. The stochastic process followed by prices depends on the forecast rules used by agents, so that the optimal choice of the forecast rule by any agent is conditional on the choices of others. An RE equilibrium imposes the consistency condition that each agent's choice is a best response to the choices of others. In the 'representative agent' models these choices are identical.

For the model [1] we have $p_t = \mu + \alpha E_{t-1}p_t + \eta_t$. Taking conditional expectations E_{t-1} on both sides and rearranging yields $E_{t-1}p_t = \bar{p} = (1-\alpha)^{-1}\mu$ and we have $p_t = \bar{p} + \eta_t$. This is the unique way to form expectations that are 'rational' in the model [1].

Two related observations should be made. First, under RE the appropriate way to form expectations depends on the stochastic process followed by the exogenous variables, η_t in the example. If these are not *iid* processes then the RE will themselves be random variables, and they often form a complicated stochastic process. Second, neither static nor AE are in general rational, except in special cases.

Next, we consider some key aspects and implications of RE models.

Forward-Looking Character

In the cobweb model, expectations pertain only to current prices. Most economic models have forward-looking elements, so that expectations about future periods appear. A simple example is the Cagan model of inflation which postulates that the demand for money depends linearly on expected inflation

$$m_t - p_t = -\psi\left(p_{t+1}^e - p_t\right) + \zeta_t, \quad \psi > 0$$

Here m_t is the log of the money supply at time t, ζ_t is an *iid* money demand shock with zero mean, p_t is the log of the price level at time t, and p_{t+1}^e denotes the expectation of p_{t+1} formed in time t. Solving for p_t we get the equation

$$p_t = \alpha p_{t+1}^e + \beta m_t + v_t \qquad [2]$$

where $\alpha = \psi(1+\psi)^{-1}$, $\beta = (1+\psi)^{-1}$, and $v_t = -(1+\psi)^{-1}\zeta_t$. Note that $0 < \alpha < 1$ and $\beta = 1-\alpha$.

The same formal model arises in other contexts, e.g., the standard model of asset pricing with risk neutrality takes form [2] for suitable α and β. Under RE the model is

$$p_t = \alpha E_t p_{t+1} + \beta m_t + v_t \qquad [3]$$

If m_t follows an exogenous stochastic process, one can show that the expression

$$p_t = v_t + \beta \sum_{i=0}^{\infty} \alpha^i E_t m_{t+i} \qquad [4]$$

solves the model, provided the sum converges. Given a specific stochastic process for m_t, it is possible to compute the forecasts $E_t m_{t+i}$ and hence the RE solution [4].

An important feature of [4] is its forward-looking character. Current price is a sum of expected values of future money stocks. If, for example, there is a change in monetary policy that is anticipated to lower the money stock from some specified future date $T > t$, this will be reflected in the price level already at time t. Previously unexpected changes in the policy rule affect p_t from the moment they become known.

More general models than [3] allow for a dependence on lagged values of the endogenous variable p_t, expectations formed at different times and over various horizons, and more general exogenous processes. Generalizations to multivariate frameworks are particularly important in practice.

A number of techniques are available for obtaining solutions under RE. Undetermined coefficient methods are often particularly convenient. Frequently, as in the model [3] with $|\alpha| < 1$, there is a unique nonexplosive solution, given nonexplosive exogenous variables. In this case, the Blanchard–Kahn or other methods can be used to compute this solution.

Policy Evaluation: The Lucas Critique

During the 1950s and 1960s applied macroeconometric models explicitly or implicitly assumed that expectations were given by AE or by some related lag scheme. The estimated systems were used for policy analysis by evaluating the effects of alternative policies. This implicitly assumed that the estimated coefficients reflect a structure that is invariant to alternative policies. Lucas criticized this approach in a 1976 paper (see Lucas, 1981). He argued that if expectations are rational, then the coefficients relating target variables to policy instruments will change when the policy process changes.

As an example, consider the Cagan model [3] with $\beta = 1-\alpha$ and assume that money supply follows the rule

$$m_t = \mu + \rho m_{t-1} + w_t \qquad [5]$$

where $|\rho| < 1$ and w_t is white noise. In this case the solution [4] reduces to

$$p_t = \delta + \gamma m_t + v_t, \quad \text{where} \qquad [6]$$

$$\delta = (1-\alpha\rho)^{-1}\alpha\mu \quad \text{and} \quad \gamma = (1-\rho\alpha)^{-1}(1-\alpha) \qquad [7]$$

The 'traditional' approach to policy would estimate δ and γ from historical data and use the estimated version

of [6] to evaluate the effects of alternative policy sequences m_t on the price level. But it is clear from [7] that γ is not invariant to the policy rule since, for example, a change in the policy parameter ρ affects the value of γ. Thus, under RE the response of p_t to m_t depends on the form of the policy rule.

The effect of the 'Lucas critique' has been to shift attention to estimation of deep parameters (such as α in the above example), which do remain invariant to policy changes and to use these estimates to evaluate alternative policy rules under RE.

Estimation and Testing of RE Models

When data on expectations are not available, it is still often possible in the context of structural models both to estimate the models under the assumption of RE and to test the RE assumption. In this case the RE assumption is being jointly tested with the model. A simple example is the Cagan model [3] with money supply rule [5]. Equations [5] and [6] can both be estimated, but [7] implies nonlinear cross-equation parameter restrictions imposed by the RE hypothesis. The system can be estimated under these overidentifying restrictions. The restrictions can also be statistically tested, in effect testing RE jointly with the model.

Closely related is the estimation and testing of *Euler equations*. These are dynamic equations, relating e.g., current consumption to expected future consumption and interest rates, which arise as optimality conditions from dynamic utility maximization. Under RE testable overidentifying restrictions again arise.

Multiple Equilibria and RE

Many RE models can have multiple equilibria. The existence of rational speculative bubble solutions besides the fundamental equilibrium illustrates this phenomenon. The standard model of asset pricing is formally identical to the Cagan model [2] if we set $v_t \equiv 0, \beta = 1, \alpha = (1+r)^{-1}$, where r is the real net interest rate. Here m_t represents the dividend at t and p_t is the price of the asset. Then [4] is called the 'fundamental solution,' i.e., the present value of anticipated future dividends. A 'rational bubble solution' is the sum of the fundamental solution and a bubble, which is any process B_t satisfying $E_t B_{t+1} = \alpha^{-1} B_t$. The bubble solutions are 'explosive' since $0 < \alpha < 1$, and macroeconomists are often content to assume away 'explosive bubbles.' In models with carefully elaborated microfoundations, explosive solutions can often be ruled out theoretically. However, the empirical issue of whether rational (or near-rational) bubbles affect asset prices is much debated.

Other models have multiple RE solutions, none of which are explosive. For example, consider the model [3] with $|\alpha| > 1$. This case can arise from linearized versions of the overlapping generations model of money under some specifications of preferences. If m_t is *iid* with mean $\overline{m}$, from eqn [4] there is the RE solution

$$p_t = (1-\alpha)^{-1}\alpha\beta\overline{m} + \beta m_t + v_t \qquad [8]$$

However, there are also well-behaved nonexplosive solutions of the form

$$p_t = \alpha^{-1}p_{t-1} - \beta\alpha^{-1}m_{t-1} - \alpha^{-1}v_{t-1} + \varepsilon_t \qquad [9]$$

where ε_t is an arbitrary process, observable at time t and satisfying $E_{t-1}(\varepsilon_t) = 0$.

The variable ε_t in [9] is often called a 'sunspot' variable and the corresponding equilibrium a 'sunspot solution.' The term sunspot is used to indicate the arbitrary nature of the variable. The solution depends on ε_t only because everyone believes that it does. It does not appear in the basic model structure. Guesnerie (2001) provides a review of sunspot equilibria and endogenous fluctuations.

Sunspot solutions have been shown to exist in overlapping generations models with carefully constructed microfoundations. More recently it has been shown that, with increasing returns to scale and monopolistic competition, sunspot solutions can exist in variations of common business cycle models. These models raise the possibility that business cycle fluctuations may be due to random but rational fluctuations in household and firm expectations, which act as a 'self-fulfilling prophecy.' The empirical significance of self-fulfilling prophecies remains an open issue.

The preceding examples involve linear models. Other types of multiplicity of RE solutions arise in nonlinear models. Many nonlinear models can be put in the general form $y_t = F(y^e_{t+1})$, where random shocks have here been omitted for simplicity. If y_t is increasing in y^e_{t+1} there may be multiple steady states satisfying $\overline{y} = F(\overline{y})$ i.e., that occur at the intersections of the graph of $F(.)$ and the 45° line. This possibility can arise in models with increasing returns to scale in production, externalities, or monopolistic competition. y is often a measure of output or aggregate economic activity and the low steady states represent inefficient 'coordination failures.' Other specifications of model $y_t = F(y^e_{t+1})$ can have multiple perfect foresight equilibria taking the form of regular cycles in addition to a steady state.

Nonlinear models can also exhibit sunspot equilibria, taking the form of a finite-state Markov process. For example, in models with two steady states it can be shown that there are RE solutions, depending on a two-state Markov sunspot process, in which the solution alternates randomly between values near the perfect foresight steady states.

Learning and Expectations

The RE approach presupposes that firms and households have a great deal of knowledge about the economy. Even in simple examples, computing the RE coefficients requires full knowledge of the model structure, the values of its parameters and those of the stochastic process of the exogenous shocks. In empirical work economists do not themselves know the parameter values and must estimate them econometrically. A more plausible view of rationality might thus be that the agents also act like statisticians or econometricians when doing the required forecasting. This insight is the starting point of the adaptive learning approach to modeling expectations formation.

Taking this approach immediately raises the question of its relationship to RE. In many cases learning can provide at least an asymptotic justification for the RE hypothesis. For example, in the cobweb model [1], if agents estimate an unknown constant expected value by computing the sample mean from past prices one can show that expectations will converge over time to the RE value. In more general models convergence to RE can occur if agents use the appropriate econometric functional form and run regressions in the same way that an econometrician might.

Another advantage of the learning approach arises when there are multiple equilibria. Consider versions of the model [3] above in which there are two types of solutions [8] and [9]. For the pure RE approach this is a conundrum. Which solution should we and the agents choose? Similarly, in nonlinear models of the form $y_t = F(y^e_{t+1})$ with multiple steady states, cyclic solutions, or sunspots, one can ask which equilibria are stable under learning. The adaptive learning approach provides answers to all these questions, as discussed in the next section.

Finally, the process of learning adds dynamics that are different from RE dynamics. In the examples, just described these dynamics disappear asymptotically. However, there are various situations in which one can expect learning dynamics to remain important over time. For example, if the economy undergoes structural shifts from time to time then agents will need periodically to relearn the relevant stochastic processes. Recent research suggests that these new dynamics can be of empirical importance; see Evans and Honkapohja (2013: Section 2.3) for an overview.

Statistical Approach to Learning

In the adaptive learning approach economic agents behave like statisticians or econometricians when forecasting economic variables needed in their decision-making. At each time the economy is in a temporary equilibrium in which the current state of the economy depends on expectations. The learning approach to expectations formation makes the forecast functions and estimation of their parameters explicit. A novel feature of this approach is that expectations and forecast functions influence future data points.

As an illustration, consider again the cobweb model [1]. Assume agents believe the stochastic process for the market price takes the form $p_t = \text{constant} + \text{noise}$ i.e., the same functional form as the RE solution. The sample mean is the standard way for estimating an unknown constant. Combining the sample mean with eqn [1] leads to a fully specified stochastic dynamical system. It can be shown that the system under learning converges to the RE solution if $\alpha < 1$.

If the economic model incorporates exogenous or lagged endogenous variables, it is natural for agents to estimate the parameters of the perceived process by means of least-squares regressions. For example, suppose an observable exogenous variable w_{t-1} is introduced into the cobweb model, so that eqn [1] becomes

$$p_t = \mu + \alpha p^e_t + \delta w_{t-1} + \eta_t \qquad [10]$$

The unique RE solution is $p_t = \bar{a} + \bar{b} w_{t-1} + \eta_t$, where $\bar{a} = (1-\alpha)^{-1}\mu$ and $\bar{b} = (1-\alpha)^{-1}\delta$ and the corresponding rational forecast is $E_{t-1}p_t = \bar{a} + \bar{b} w_{t-1}$.

If RE is not postulated, it is natural to assume agents forecast price as a linear function of the observable w_{t-1}. Under least-squares learning the forecast of agents is

$$p^e_t = a_{t-1} + b_{t-1} w_{t-1}$$

where a_{t-1} and b_{t-1} are parameter estimates obtained by a least-squares regression of p_t on w_{t-1} and an intercept, using the data available through time $t-1$. It can be shown that (a_t, b_t) converges to the unique RE equilibrium (REE) given by $(\bar{a}, \bar{b})$ if $\alpha < 1$.

Least-squares learning can be generalized to allow for priors on the initial forecast model parameters, and implemented by recursive forms of Bayesian updating. Bayesian learning procedures can also allow for perceived parameter drift.

Stability under Learning

When expectations are modeled by least-squares learning there is convergence to the REE as $t \to \infty$ provided a stability condition is met. This condition can generally be obtained by the expectational stability (E-stability) approach, see Evans and Honkapohja (2001).

To illustrate this approach for the cobweb model [10], suppose expectations are based on the *Perceived Law of Motion* (PLM) $p_t = a + b w_{t-1} + \eta_t$ and hence given by $p^e_t = a + b w_{t-1}$, where (a, b) may not be the REE values. Substituting this into [10] we obtain the corresponding *Actual Law of Motion* (ALM).

$$p_t = (\mu + \alpha a) + (\delta + \alpha b) w_{t-1} + \eta_t$$

This yields a mapping from the PLM parameters (a, b) to the ALM parameters $T(a, b) = (\mu + \alpha a, \delta + \alpha b)$. At the REE $(\bar{a}, \bar{b})$ we have $T(\bar{a}, \bar{b}) = (\bar{a}, \bar{b})$. Expectational stability looks at whether the REE is the outcome of a process in which the parameters of the PLM are adjusted slowly toward the parameters of the induced ALM. Convergence requires fulfillment of the E-stability condition, which in the cobweb model is $\alpha < 1$. For details see Evans and Honkapohja (2001).

Even in fairly complicated models it is often straightforward to compute E-stability conditions and these appear quite generally to govern convergence of statistical learning rules. Local stability under adaptive learning provides a selection criterion in models with multiple RE equilibria. For example, in the nonlinear model $y_t = F(y^e_{t+1})$, only steady states with slope $F'(\bar{y}) < 1$ are E-stable. This model can also have sunspot solutions and an appropriate form of adaptive learning can converge to rational sunspot equilibria, provided the corresponding E-stability condition is satisfied, see Evans and Honkapohja (2001).

Other Approaches and Further Issues

Some other recent approaches to modeling expectation formation are closer to RE than adaptive learning. In 'eductive learning' agents engage in a process of reasoning using common knowledge assumptions and the learning takes place in logical or notional time, e.g., see Guesnerie (2005). In the cobweb model [1] it can be shown that if agents are fully rational and have full understanding of the structure, and if this is common knowledge, then such hyperrational agents will coordinate on the REE if $|\alpha| < 1$.

Another approach that retains aspects of RE but assumes costs and constraints to agents from acquisition of information is called rational inattention (or sticky information) in the recent literature, e.g., see Sims (2011) for a review.

In contrast, the adaptive learning approach assumes a form of bounded rationality. Bounded rationality in learning may result from pertinent issues in real-world forecasting. For example, applied econometricians do not know the true data-generating process. This usually implies that their forecasting models involve misspecification and heterogeneity. Another difficulty is structural change of unknown form that takes place in the economy. The recent literature has introduced these aspects into the adaptive learning approach.

Misspecification and heterogeneity raise the possibility that agents choose between competing forecasting models with the predictive performance of competing models influencing the choice of the model over time. This gives rise to the 'dynamic predictor selection' approach. This choice might also be between heuristic forecasting models, as in Hommes (2013). Another natural approach when multiple models are in play is that agents do some kind of forecasting model averaging.

If structural change of unknown form is a concern, a natural approach is to employ learning rules, such as constant gain algorithms, that can track structural changes more accurately than least-squares algorithms. Constant gain algorithms do not converge fully to an RE equilibrium even if the economic structure is in fact constant. The estimated parameter values contain some randomness asymptotically. In some cases these procedures can lead to escape dynamics in which parameter estimates stray far from the RE solution for an extended period.

The central message from the modified learning procedures just discussed is that variations of econometric learning, which reflect real-world concerns, can lead to new learning dynamics that are qualitatively different from RE dynamics. For example, regime switching and increased volatility can be explained by these procedures. An overview and references to the issues reviewed in this section is provided in Evans and Honkapohja (2013: Sections 2.2.2 and 2.4.2).

Economic Applications

Imperfect knowledge and learning have recently been shown to have major implications to a number of areas in macroeconomics and finance. For overviews of and references to the topics discussed in this section, see Evans and Honkapohja (2013: Sections 2.3, 2.4.2, and 2.5.

The learning viewpoint in the equilibrium models of business cycle fluctuations can mitigate implications of the RE hypothesis that do not match the empirical data. The influence of anticipations of government policies on the outcomes of policies, much emphasized by the RE hypothesis, also appears with adaptive learning by private agents who have knowledge of future policies but the learning dynamics can be quite different. Interestingly, Ricardian equivalence for fiscal policy financing may or may not hold under learning depending on the detailed assumptions.

The learning viewpoint has contributed to thinking about macroeconomic policy, given its role as a source of macroeconomic dynamics. Facilitating stability of private-sector learning is clearly an objective for monetary policy design and this has implications for the formulation of both Taylor-type empirical rules and optimal policy rules. Analysis of exceptional situations involving either rapid inflation or economies with 'liquidity traps' at near-zero interest rates and low or negative inflation has also benefited from the learning viewpoint. These situations are challenging for fiscal policy as well as monetary policy. For a review see Evans and Honkapohja (2009, 2013).

In finance, learning models provide a natural explanation for empirical aspects of stock prices such as mean reversion, excess volatility, persistence, and long-term predictability, which are problematic under RE. Learning has also been employed in recent research on speculative bubbles of asset prices, and can help in overcoming the forward premium puzzle in the empirics of exchange rates, as well as issues of volatility shifts and persistence.

Empirical Issues in Expectations Formation

In Section Economic Applications we discussed economic applications in which models of expectations play a central role. In addition there is extensive research that considers different aspects of empirical data on expectations and aims to test empirically different models of expectation formation.

Testing for Rationality

Given its prominence, testing for rationality is of special interest. If the RE hypothesis is correct, then expectations obey very strong assumptions. Specifically, the orthogonality principle states that if a forecast f_t of a variable p_t, is made based on information set I_{t-1}, then under RE the forecast errors $e_t = p_t - f_t$ must satisfy $E(e_t|I_{t-1}) = 0$. If survey data for f_t is available, the test for RE can be implemented by a regression $e_t = \phi' z_{t-1} + u_t$, where z_{t-1} is a vector of variables in I_{t-1}, and testing the null hypothesis $\phi = 0$.

In practice tests of rationality use survey data on forecasts (see the next section) and the tests typically lead to rejections of rationality, though the interpretation of these results is controversial. While various interpretations are possible, one possibility is that rejections of rationality arise from agents deviating from full RE due to learning, forecasting costs, and/or strategic uncertainty.

Fitting Survey Data on Expectations

There are numerous extensive data sets on expectations of macroeconomic time series, including the EU Commission Consumer Survey, the ECB Survey of Professional Forecasters, the FRB Philadelphia Survey of Professional Forecasters, and the University of Michigan Survey of Consumer Attitudes and Behavior. These survey data are regularly monitored and used in forecasting for economic decision and policy making in practice.

In economic research, these survey data have been used to estimate macroeconomic models in which expectation variables are explicitly included, for an example see Orphanides and Williams (2012). Another use of this data has been testing alternative hypotheses about the expectation formation process, see Pesaran and Weale (2006) and Sinclair (2010) for reviews and recent research.

Using Economic Frameworks to Extract Expectations

Survey data are very important as they provide direct measurements of expectations. The main alternative to measuring expectations is to employ economic models and other data to obtain measurements of expectations. There are two main approaches using this methodology.

Indirect measures of inflation expectations can be obtained from asset market data. The existence of a range of assets, such as indexed and nonindexed bonds, bonds of different maturities, interest rate swaps, and other inflation-indexed derivative assets, the processes of which respond differently to inflation expectations or to expectations of future interest rates, make it possible to extract the inflation or interest rate forecasts of market participants from financial market data. These forecasts are regularly used as information in economic and financial decision-making. A challenge in this data is the need to separate mean dynamics from a risk premium that can vary over time. See Christensen et al. (2010) for an example of measuring inflation expectations and risk premia from bond market data.

The other main methodology to elicit forecasts of economic variables is to employ laboratory experiments. A large literature has recently developed in this area. See, for example, Hommes (2013). One of the main purposes is to use this experimental data to test aspects of expectation formation in a population of agents. These experiments can also investigate the types of economic dynamics that can emerge in models with expectations.

Experiential Psychotherapy

Leslie S Greenberg, York University, Toronto, ON, Canada

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Experiential therapy focuses on promoting in-therapy experiencing of what is being talked about. Methods that stimulate emotional experience are used within the context of an empathic facilitative relationship. People are seen as active agents in the construction of their own realities and the self is seen as a process in a continual state of self-organization. The goal of treatment is to promote self-reorganization by integrating disparate parts of the self and by increasing awareness. Awareness of the processes that regulate what enters awareness and what does not is also emphasized. Experiential theorists have specified patterned sequences of change processes that occur in sessions, sequences such as attending to bodily felt sensation, arousing emotion followed by accessing needs. They attempt to facilitate these steps in therapy sessions. The therapist is seen as an expert in the use of methods that promote experiencing and facilitate new steps rather than as an expert on what people are experiencing. In addition, I–thou dialogues between client and therapist about experiences in the relationship are also seen as an important focus of therapeutic work.

Introduction

The term *experiential* is defined in the *Concise Oxford Dictionary* (1990) as "involving or based on experience" and experience is defined as the "actual observation of, or practical acquaintance with, facts or events" or "to feel or be affected by (an emotion, etc.)." A distinction between two ways of knowing, knowledge by acquaintance and knowledge by description, first made by St Augustine, and later emphasized in the epistemologies of William James and Bertrand Russell, helps describe the essence of experiential therapy. Experiential therapy is an approach to therapy that focuses on promoting knowledge by acquaintance. Here a person does not come to know something about him- or herself conceptually but rather has an emotional experience of it. In experiential therapy, the clients' experiencing process is kept as a continuous point of reference for all therapist responses and change is seen as occurring by the promotion of new in-session experience.

Although the term experiential therapy first arose to refer to Whitaker and Malone's approaches to psychodynamically oriented family and individual therapy (Whitaker and Malone, 1953), this approach has subsequently grown out of a variety of 'third force,' humanistic, approaches. These include client-centered (Rogers, 1959), Gestalt (Perls et al., 1951), and existential therapy (May and Yalom, 1995), as well as other approaches that emphasize working with the clients in-therapy experiencing process (Greenberg et al., 1998). Experiential therapy consists of those approaches that, within the context of a facilitative human relationship, focus on the creation of new meaning by the symbolization of experience in awareness. The two major foci of experiential therapy practice are the personal presence of the therapist in the provision of an emphatic and facilitatively genuine therapeutic relationship, and increasing clients' awareness of internal experience by focusing them on their moment-by-moment subjective experience.

View of Human Nature and Functioning

Experiential therapy adopts an existential view of human nature, one that sees existence as preceding essence. People are seen as active agents in the construction of their own realities and choice is seen as the final arbiter in human functioning. Individuals are seen as being born morally neutral with a penchant both for health and sickness, and good and bad. What is essential, however, is that people are seen as having innate worth, the ability to know the difference between good and evil, and the capacity to choose. Free will thus is the foundational principle and therapy involves facilitation of the actualization of the potential for healthy functioning. Health is seen as arising from the ability to symbolize experience in awareness and to integrate different parts of the self to create equilibrium and coherent meaning.

Experiential theory of personality proposes a process model of the self. The self is seen as a dynamic experiential system that is in a continual process of self-organization, i.e., organizing at any moment as the self one finds oneself to be as for example confident, unsure, humorous, or serious. Experiential theory is constructivist in nature and adopts a dynamic and dialectical view of human functioning. It emphasizes that meaning is created by human activity, in dialogue with others, that change is an inherent aspect of all systems, and that this occurs by a synthesis of parts. Meaning construction is viewed as being constrained by a bodily felt emotional experience but as influenced by language and culture and ultimately as created by a synthesis of experience and symbol (Gendlin, 1962; Greenberg et al., 1993; Greenberg and Pascual-Leone, 1995, 1997). Emotional experience is seen as both creating and being created by its conscious symbolization and expression. This view casts people as creators of the self they find themselves to be. In addition, experiential therapy, by adopting a relational view of functioning, sees the self as coming into existence at the boundary between inside and outside, between organism and environment, by a synthesis of bodily experience, symbol, and interpersonal validation.

Emotional experience, although seen as a basically healthy resource, is viewed as capable of either providing healthy adaptive information based on its biologically adaptive origins or, in certain instances, as having become maladaptive through learning and experience. The most basic process for the individual in therapy is thus one of developing awareness of emotion and discriminating which emotional responses are

healthy and can be used as a guide, and which are maladaptive, and need to be changed.

Goals

The general goals of treatment are to promote more adaptive, dynamic organizations and integrative self-organizations. Therapy focuses on the whole person, i.e., it is person-centered rather than problem- or symptom-focused, but within this holistic focus, the underlying determinants of different types of self-dysfunction are also an important point of focus. Thus both a change in manner of functioning of the whole self and changes in particular problems in self-organization are viewed as important. For example, a client may be seen as changing the manner of functioning both by becoming more empathic to the self and by being able to symbolize bodily felt experience, as well as changing by resolving a specific problem such resolving unfinished business with a significant other. Thus, treatment in addition to promoting self-acceptance and strengthening of the self also aims at solving particular problems of self-organization that emerge in treatment. The problems that are focused on emerge in a collaborative fashion over the course of treatment.

Basic Principles of Practice

Experiential therapy recognizes both the power of the understanding relationship and the importance of different in-therapy tasks in promoting different types of therapeutic change. The quality of the bond between participants as well as collaboration on the tasks and goals of therapy are seen as essential in creating a good therapeutic alliance. The bond is warm, respectful, empathic, and validating, while the goals and tasks focus on increasing awareness, deepening experience, and resolving specific in-session emotional problems.

The relational bond is seen as involving three main healing ingredients: first, a more transcendent aspect, the human *presence* of the therapist, witnessing and validating the other's humanness; second, a set of more explicit facilitative *attitudes* that create a safe working environment; and third, a set of specific interpersonal *behaviors* that facilitate growth and provide new interpersonal experience. Buber's (1958) 'I–thou' relationship, involving such elements as presence, commitment to dialogue, and nonexploitiveness, and the Rogerian triad (Rogers, 1957) of empathy, positive regard, and congruence together describe the general nature of the relationship. Empathy is seen as a complex cognitive/affective process of imaginative entry into the world of the other and involves understanding, in addition to being with, the other and the promotion of deeper experience. This process helps the client to feel connected, to regulate affect, and to construct new meaning.

A relational bond of this type is seen as both confirming the client as an authentic source of experience and as providing the optimal context for helping the client to attend to and become aware of implicit, not yet symbolized experience and to communicate and explore it without fear of evaluation. The facilitative relationship, in addition to being curative in and of itself, also provides a safe environment for working on particular problems. Finally, not only does the relationship serve as a confirming environment and as a context for specific forms of intrapsychic work, but it is itself also a medium for specific corrective interpersonal experiences. Thus, certain forms of work on the relationship between client and therapist are also seen as mutative.

In addition to the provision of a 'healing' relationship, facilitating work on particular therapeutic tasks is also seen as a core ingredient of experiential therapy (Greenberg et al., 1993). The most central task of experiential therapy is that of deepening the clients' experience. This involves helping clients focus on their internal experience, helping them to symbolize it in words, and creating a new meaning. The therapist promotes different internal processes at different times to aid experiential processing. The processes facilitated range from symbolizing a bodily felt sense, to evoking memories, to letting an intense feeling form, to expressing feelings, to reflecting on experience to create new meaning. The client in addition is encouraged to engage in such activities as psychodramatic enactments or exercises in imagination to help address particular emotional issues. Specific tasks such as resolving problematic reactions or resolving splits between parts of the self are worked on in therapy. Resolving problematic reactions, for example, involves re-evoking the situation in a vivid manner in order to reexperience what occurred in order to develop a new view of the self and situation. Resolving splits involves the promotion of separation and contact between two parts of the self in a dialogue to facilitate self-acceptance. In these tasks, the client is seen as an active agent engaging in an exploratory process, and the tasks are viewed as being done *by* clients rather than done *to* them.

A Process Theory

An important distinguishing characteristic of experiential therapy is that it offers a process theory of how to facilitate knowledge of acquaintance, rather than a content theory of personality or psychopathology. A process theory of this type specifies both the moment-by-moment steps in the client's process of change and the therapist interventions that will facilitate these steps. The emphasis in each step always is on how to promote the direct sensing of what is concretely felt in the moment to create new meaning.

There is an explicit assumption that within each individual there is a flow of experiencing to which the person can refer to in order to be informed about the personal meaning of particular experiences. The main principle of the experiential method is to have people check whatever is said or done against their own concretely felt experience. Change is seen as emerging from a growing awareness of previously unsymbolized experience and the bringing of this experience into dialectical interaction with words or symbols and other aspect of experience to create new meaning.

The key to experiential therapy is to have clients experience or become acquainted with any manner of content in a new way such that this new experience will produce a change in the way they view themselves, others, and the world. Experiential therapy thus adds to the other approaches the emphasis that

symbols, schemes, and even behavior must interact with the body based, experiential, level of existence in order to produce change. It thus offers a process theory of how body and symbol interact and a set of methods for promoting this process.

Experiential therapy theorists have specified patterned sequences of change processes and events, the explicit connections of which are spelled out by their experiential theories of change. Three such characteristic sequences are described. One sequence offered by Gendlin (1996) includes three fundamental client change events: the client focuses on a directly felt meaning; the client allows feelings, words, and pictures to arise from this inward focusing, and attends to the generated feeling; and the client receives a new felt meaning that emerges from the ensuing shift in body experience. Another experiential sequence (Mahrer, 1989) consists of four client basic change events: the client attains a level of strong feeling; the client welcomes and appreciates the accessed inner experiencing; the client becomes the inner experiencing in the context of earlier life scenes; and the client becomes and behaves according to the inner experiencing in the context of imminent future life scenes.

A third sequence for transforming distressed feelings (Greenberg and Paivio, 1997; Pascual-Leone and Greenberg, 2007) involves changing emotion with emotion (Greenberg, 2010). The process begins with a client in a state of emotional distress, feeling pain, hopeless, helpless, complaint, self-pity, confused, despair, or some other distressing secondary emotional experience. When clients in a state of global distress begin to elaborate and differentiate their thoughts and feelings they subsequently move into maladaptive fear and shame or the sadness of lonely abandonment. The path to resolution involves accessing the unmet in the painful emotion and this helps activate assertive anger or self-soothing and the expression of grief or hurt. All this facilitates a sense of acceptance and agency (Pascual-Leone and Greenberg, 2007).

Transformation occurs when maladaptive states are differentiated into *adaptive needs* which act to refute the core *negative evaluations* about the self embedded in the core maladaptive schemes. The inherent opposition of these two experiences "I am not worthy or lovable" and "I *deserve* to be loved or respected" in response to the same situation is overcome by the creation of new meaning in which a new more *positive evaluation* of the self emerges. Throughout the process of transformation, moderate to high emotional arousal is necessary but at a level that remains facilitative of the healing process. The therapist thus needs to facilitate emotional arousal but not so much that it is dysregulating or disorienting.

In these processes, the therapist is seen as an expert on how to facilitate new steps in the client's experience rather than an expert on the content of the client's experience. Therapists thus avoid interpretations of the content of a client's experiences that tell the patient why he or she does things and that are theory-driven rather than experience-near. Responses that are conceptual or explanatory, or are expressed as fact, or that give the message that truth comes from the therapists' professional knowledge are avoided in favor of phenomenologically refined exploration of the client's experience. Experiential therapy thus attempts to eliminate any interpretations that are based on the therapist's theory of how people are, or should be, or those that attempt to reveal hidden 'truths.'

The experiential approach rather places great emphasis on, and respect for, what the patient experiences, and pays special attention to what the patient experiences in the relationship with the therapist. Experiential therapy involves consistent listening from within the patient's frame of reference. Hence sustained empathic inquiry is a central part of the practice. However, although this empathic emphasis is necessary for good psychotherapy, it is not necessarily sufficient for the best psychotherapy. The most effective psychotherapy also requires therapist practices of a technical nature, such as phenomenological focusing, experimentation, and behavioral observation (Gendlin, 1996; Perls et al., 1951). Diagnostic understanding of the individual, and also understanding the social, cultural, and institutional forces affecting the individual, is required.

Notwithstanding the fact that what the patient experiences is the indispensable essence of psychotherapy, and that it is imperative that this be the subject of respectful ongoing inquiry by therapist and patient, what the patient does not experience is also an indispensable and critical component of what happens in therapy. Important factors that are kept from the patient's conscious experience that do not become figural in awareness also need to be the subject of phenomenological exploration. In experiential therapy, there is a special emphasis on bringing into awareness the processes that regulate this process of awareness/unawareness (Polster and Polster, 1973; Yontef, 1993). This work is codirected by therapist and patient and is not based on any alleged higher truth of the therapist. It is based on a joint empathic exploration that may include observation, experimentation, and dialogue.

Conclusion

In the experiential approach, an empathic focus on the patient's actual experience is seen as indispensable, but the therapist is also seen as making contributions in addition to sustained empathic inquiry. Therapists complement the empathic inquiry with a variety of therapeutic interventions that can help the patient learn how efficiently to focus awareness and distinguish actual phenomenological experience that can highlight the processes essential to the patient's characterological organization by sophisticated and competent understanding that includes understanding theories of healthy functioning and psychopathology.

Experiential therapy has been demonstrated to be effective in treating depression, anxiety, childhood maltreatment, and marital distress in addition to some personality disorders and a variety of other problems in living (Greenberg et al., 1994, 1998).

Abstract

This article provides an overview of experimental design using a Bayesian decision-theoretic framework. Scientific experimentation requires decisions about how an experiment will be conducted and analyzed. Such decisions depend on the goals and purpose of the experiment, but certain choices may be restricted by available resources and ethical considerations. Prior information may be available from earlier experiments or from conjectures which motivate the investigation. The Bayesian approach provides a coherent framework where prior information and uncertainties regarding unknown quantities can be combined to find an experimental design that optimizes the goals of the experiment.

This article provides an overview of experimental design using a Bayesian decision-theoretic framework. Scientific experimentation requires decisions about how an experiment will be conducted and analyzed. Such decisions depend on the goals and purpose of the experiment, but certain choices may be restricted by available resources and ethica1 considerations. Prior information may be available from earlier experiments or from conjectures which motivate the investigation. The Bayesian approach provides a coherent framework where prior information and uncertainties regarding unknown quantities can be combined to find an experimental design that optimizes the goals of the experiment.

Introduction

Experimentation plays an integral part in the scientific method. Conjectures and hypotheses are put forth based on the current state of knowledge. Experimental data may be collected to address unknown aspects of the problem. Finally, analysis of experimental results may lead to one hypothesis being favored over others or may lead to new questions and investigations, so that the process is repeated, with the accumulation of additional knowledge about the scientific process under investigation.

In some fields of scientific inquiry, physical models can be used to describe the outcome of an experiment given certain inputs with complete certainty. In the majority of applications, one cannot describe the scientific phenomena perfectly, leading to a distribution of possible outcomes, which can be described by probability models. For example, in comparing a new therapy to an existing treatment, individuals receive one of two treatments. The outcome or response is an indicator of 'success' or 'failure' of the given treatment, which can be modeled using Bernoulli distributions with unknown success probabilities. In psychological or educational testing, the outcome may be scores on a battery of tests. The outcomes or responses may depend on many other factors besides the assigned treatment, such as age, education, gender, or other explanatory variables. Hypotheses or quantities of interest are often phrased in terms of parameters θ of statistical models which relate the distribution of outcomes Y to levels of explanatory variables.

In conducting an experiment, there are many design issues to resolve, including deciding which treatments to study, which factors to control, and what aspects of an experiment to randomize. Other aspects of experimental design – such as how many experimental units are needed, how many observations should be allocated to each treatment, or what levels of other input or control variables should be used – have traditionally fallen under the umbrella of statistical design (see Experimental Design: Overview). Because of costs, ethics, or other limitations on resources or time, sample sizes are usually restricted, and efficient use of available resources is critical. The purpose of optimal experimental design is to improve statistical inference regarding the quantities of interest by the optimal selection of values for design factors under the control of the investigator, within, of course, the constraints of available resources. Decision theory provides a mathematical foundation for the selection of optimal designs. Prior information from earlier related experiments, observational studies, or subjective beliefs from personal observations, can be valuable in deciding how to allocate treatments efficiently, leading to more informative experiments. The Bayesian approach to experimental design provides a formal way to incorporate such prior information into the design process.

Bayesian Optimal Designs

The statistical aspects of an experiment e may be formally described by the sample space Ω (possible outcomes for the response Y), the parameter space Θ, and a probability model $p_e(y|\theta)$ that represents the distribution of observable random variables Y indexed by a parameter θ, an element of the parameter space Θ. Sample sizes, treatment levels, number of treatments, levels of explanatory variables, or other aspects of the design to be selected are implicitly contained in $p_e(Y|\theta)$. The primary goal(s) or terminal decision(s) of an experiment may include, but are not limited to, estimating θ or other quantities of interest that are functions of θ, predicting future

observations, selecting among competing models, or testing other hypotheses.

Lindley presented a two-part decision theoretic approach to experimental design, which provides a unifying theory for most work in Bayesian experimental design today. Lindley's approach involves specification of a suitable utility function reflecting the purpose and costs of the experiment; the best design is selected to maximize expected utility. In this framework, an experiment e is selected from the possible collection of experiments E (the first decision problem). After choosing an experiment e, outcomes Y are observed. Based on the observed data Y and experiment e, a terminal decision d is selected from possible decision rules D, which addresses the terminal goal(s) of the experiment. A utility function in the form $U(d, \theta, e, Y)$ encodes the costs and consequences of using experiment e and decision d with data Y and parameter θ. Assuming that the goals of an experiment and terminal decision can be formally expressed through a utility function, the Bayesian solution is to find the best design and best decision rule that maximize expected utility.

While the process of experimentation followed by inference/decision making proceeds in time order, it is easier to solve the optimal decision problem in reverse time order. The terminal-stage decision problem involves finding the best decision rule d given the observed data Y under experiment e that maximizes the *posterior* expected utility,

$$\max_d \int_\Theta U(d,\theta,e,Y)p(\theta|Y,e)\mathrm{d}\theta = U(e,Y) \qquad [1]$$

Here, the expectation or averaging over θ accounts for uncertainty regarding the unknown θ. The expectation is taken with respect to the posterior distribution of θ, which properly reflects uncertainty in θ at the terminal stage after Y has been observed under experiment e.

As the experiment e must be selected before data Y are observed, the second-stage optimization problem involves finding the best experiment e that maximizes the *preposterior* expected utility. The preposterior expected utility is obtained by integrating the result in Eqn. [1] over possible outcomes in the sample space Ω,

$$U(e) = \int_\Omega U(e,Y)p(Y|e)\mathrm{d}Y = \int_\Theta\int_\Omega U(e,Y)p_e(Y|\theta)p(\theta)\mathrm{d}\theta\mathrm{d}Y \qquad [2]$$

This integral is with respect to $p(Y|e)$, the marginal distribution of the data under experiment e, which is obtained by integrating $p_e(Y|\theta)$, over possible *prior* values for θ, described by prior distribution $p(\theta)$. The Bayesian solution to the experimental design problem is provided by the experiment e^* which maximizes $U(e)$:

$$U(e^*) = \max_e \int_\Omega \max_d \int_\Theta U(d,\theta,e,Y) = p(\theta|\gamma,e)p(\gamma|e)\mathrm{d}\theta\mathrm{d}\gamma \qquad [3]$$

This general formulation can be used to find optimal designs for a single experiment, and can be extended to optimal selection of a sequence of experiments and sequential decision making (Lindley 1972).

Choice of Utility Functions

It is important that utility functions be tailored to the goals of a given problem. Optimal designs for discriminating between two different models may be quite different from designs for prediction. In a one-way analysis of variance model, the best design for comparing k treatments to a control group, is not necessarily the optimal design for estimating the effects of $k+1$ treatments, as these experiments have different goals. While taking an equal number of observations in each of the $k+1$ treatment groups is a possibility, other arrangements may provide more information, particularly when data from previous experiments are taken into account. For example, several previous studies may be available using an existing therapy, but limited information may be available on a new treatment. Differential costs of treatment also need to be considered, which may lead to other allocations of sample sizes or choice of experiments. Ethical considerations may also be incorporated that may constrain the assignment of treatments (Kadane 1996).

Many of the papers in Bayesian design have based utility functions on Shannon information or quadratic loss. Motivation for these choices is discussed below. The reader is encouraged to refer to Chaloner and Verdinelli (1995) for additional details on these criteria, references, and relationships of other Bayesian utility functions to standard optimality criteria.

Shannon Information

Shannon information is appropriate for inference problems regarding θ or functions in θ, without specification of particular hypotheses. The expected utility function is based on the expected change in Shannon information or equivalently the Kullback-Leibler divergence between the posterior and prior distributions. As the prior distribution does not depend on the design, this simplifies to the expected Shannon information of the posterior distribution,

$$U(e) = \int_\Theta\int_\Omega \log\{p(\theta|U,e)\}p_e(\gamma|\theta)p(\theta)\mathrm{d}Y\mathrm{d}\theta \qquad [4]$$

thus the design goal is to find the design that maximizes the information provided by the experiment. In normal linear models with normal prior distributions, this leads to a criterion related to the well-known D-optimality from classical design,

$$U(e) \propto \log|(X_e^T X_e + R)/\sigma^2 \qquad [5]$$

where X_c is the design matrix for experiment e and R/σ^2 is the prior precision matrix (inverse of the prior covariance matrix).

If prediction of future observations is important, the expected gain in Shannon information for a future observation Y_{n+1},

$$U(e) = \int \log(p(Y_{n+1}|Y,e)p(Y_{n+1}|Y,e)p(Y|e)\mathrm{d}Y\mathrm{d}Y_{n+1} \qquad [6]$$

may be relevant. In normal linear models with prediction at a new point x_{n+1} this leads to

$$U(e) \propto \log\left[\left\{x_{n+1}^T(X_e^T X_e + R)^{-1}x_{n+1} + 1\right\}^{-1}\Big/\sigma^2\right] \qquad [7]$$

a Bayesian version of c-optimality.

Quadratic Loss

Point estimation based on quadratic loss leads to the expected utility function

$$U(e) = -\int_{\Theta}\int_{\Omega}(\theta+\widehat{\theta})^{-T}A(\theta-\widehat{\theta}) \qquad [8]$$

where A is a symmetric non-negative definite matrix. The matrix A can be used to weight several different estimation problems where interest may be in estimating individual components of θ or linear combinations of θ. Under the normal linear model and normal prior distribution this results in

$$U(e) = -\sigma^2 tr\left\{A\left(X_e^T X_e + R\right)^{-1}\right\} \qquad [9]$$

a Bayesian generalization of the A-optimality design criterion.

Other Utility and Loss Functions

Utility functions may be based on other loss functions besides quadratic loss. While a quadratic loss function may be appropriate in many cases, there are times when underestimation of a quantity incurs greater losses than overestimation. In such situations, asymmetric loss functions are more appropriate for design and inference (Clyde et al 1996). Discussion of other utility functions related to prediction, hypothesis testing and model discrimination and applications can be found in Chaloner and Verdinelli (1995).

Multiple Objectives

An experiment may often have several, possibly competing objectives which cannot be easily characterized by only one of the standard optimality criteria, and several design criteria may be appropriate. Weighted combinations of utility functions are still valid utility functions, so optimal designs for multiple objectives can be handled within the maximizing expected utility framework. For examples see Verdinelli (1992), Verdinelli and Kadane (1992), Clyde and Chaloner (1996). A difficulty with this approach is that utilities may be expressed in different scales which must be accounted for in the choice of weights. Equivalently, one can find the optimal experiment under one (primary) optimality criterion, subject to constraints on the minimal *efficiency* of the experiment under criteria for other objectives. These approaches are a potential way to address robustness of experimental designs under multiple objectives, models, and prior distributions.

Prior Distributions

Prior elicitation is an important step in designing Bayesian experiments, as well as analysis. Clyde et al (1996) use historical data from previous experiments to construct a hierarchical prior distribution to use for design of future experiments. Kadane (1996) considers many of the practical issues in subjective elicitation for clinical trials. Tsai and Chaloner (2001) describe a design problem where prior distributions are elicited from more than 50 clinical experts.

While some researchers may agree to using prior information to help design an experiment, they may want to have their final conclusions stand on their own, such as in a frequentist analysis. One of the goals of the experiment may be to convince a skeptic, who has different beliefs from the designer of the experiment, that a treatment is effective. In such cases the prior distribution used in constructing the posterior distribution $p(\theta|Y, e)$ in the expected utility Eqn. [1] for the terminal decision problem may be different from the prior distribution $p(\theta)$ used in finding the best design in Eqn. [2]. Etzioni and Kadane (1993) consider the problem of design when the designer and terminal decision maker have different prior beliefs corresponding to different decision rules.

Calculations

Calculation of expected utility, as in Eqns. [1] and [2], requires evaluation of potentially high-dimensional integrals, combined with difficult optimization problems, and in part, has limited the use of Bayesian optimal design in the practice. In normal linear models for many of the standard utility functions presented, the terminal decision rule can be solved in closed form and integrals can be computed analytically, leaving the optimization problem of finding the best experiment e^*. Except in special cases, numerical optimization must often be used to find the optimal design.

One can often relax the problem in the following way. Finding optimal 'exact' designs is often a difficult problem (similar to the traveling salesman problem). Designs can often be viewed in terms of a collection of support points (treatment levels) with weights that indicate the number of observations to be assigned at each support point. An exact design is one where the number of observations at each support point is an integer. A 'continuous' design is obtained by allowing the solution for the weights to be any real number. Rather than finding the optimal exact design, in the relaxed problem, the class of experiments is enlarged to include continuous designs. Mathematically, finding the optimal design in the continuous problem is easier to solve, and methods for checking optimality are often feasible. If the solution corresponds to an exact design, one can then show that it is the globally optimal design. While continuous designs cannot be used in practice, rounding of continuous designs provides exact solutions that are often close to optimal.

For nonlinear models, generalized linear models and other 'nonlinear' design problems (i.e., interest in nonlinear functions in an otherwise linear model), expected utility generally cannot be calculated in closed form and must be approximated. Many of the results for nonlinear design rely on asymptotic normal approximations in calculating expectations (Chaloner and Verdinelli 1995). Integrals may also be approximated by numerical quadrature, Laplace integration or Monte Carlo integration. With advances in computing resources, simulation-based optimal design is now an option, although methods often have to be designed for each specific application (see Müller 1999 for an overview of this area). As utility functions in many problems have been selected for their computational tractability,

simulation-based design may soon open the way for greater use of scientific-based utility functions that better match the goals of the experiment. Hierarchical models are becoming increasingly important in modelling latent and random effects and accounting for subject-to-subject variability, for example. Advances in Bayesian computation, such as Markov chain Monte Carlo, now mean that inference in such models can be carried out in real problems. It is becoming easier to accommodate hierarchical and other complex models in the design of experiments with simulation-based optimal design schemes. Clyde et al (1996) compare analytic approximations and Monte Carlo-based design schemes for a hierarchical binary regression model using an asymmetric loss function.

Applications

Pilz (1991) covers Bayesian design and estimation in linear models, although from a rather mathematical viewpoint. Atkinson (1996) reviews both classical and Bayesian optimal design for linear and nonlinear designs, and presents recent applications such as design for clinical trials. Chaloner and Verdinelli (1995) provide a thorough review of literature on Bayesian designs and applications, which includes experimental designs for linear models such as regression and analysis of variance models, factorial and factional factorial experiments, variance component models, mixtures of linear models, hierarchical models, nonlinear regression models, binary regression models, designs for clinical trials and sequential experimentation. The article includes several worked-out examples, including design for one-way analysis of variance. The article by Clyde et al (1996) explores simulation-based design for a hierarchical logistic regression model, and illustrates how to construct prior distributions based on previous experiments. Other examples of simulation-based design appear in Müller (1999). For an example related to social sciences, see Experimental Design: Large-Scale Social Experimentation.

The area of Bayesian design and analysis for clinical trails in both sequential and nonsequential designs is an exciting and active area, with many practical developments. For a survey of literature on sequential design, see Sequential Statistical Methods. The volume edited by Kadane (1996) describes a complete case study and discusses many of the critical issues in design and analysis of clinical trials, considering ethics, prior elicitation, randomization, treatment allocation, utilities, and decision making. Tsai and Chaloner (2001) describe the design of two large clinical trials, where prior distributions are based on eliciting prior opinions from over 50 clinicians. The design problem involves finding a sample size so that consensus of opinion is met with high probability, where consensus means that all clinicians would prescribe the same treatment based on their posterior opinions after the trial. Other recent examples include Rosner and Berry (1995), Simon and Freudman (1997).

While the increased use of Bayesian design in applications is especially encouraging, specialized software is often required. There is a growing need for reliable, user-friendly software for Bayesian design so that the methods can be more accessible and see greater applicability.

Example

The following design problem is concerned with choosing a sample size for an experiment to confirm results from an earlier study. All individuals in the first study had been diagnosed with breast cancer. Each individual had a biopsy of tumor tissue analyzed for expression levels or a protein implicated in progression of the disease; measured protein expression levels were scored between 0 and 8. All 135 individuals received a chemotherapeutic agent, with the goal of achieving pre-operative tumor regression. The measured outcome for each subject was a binary indicator of tumor regression. The researchers expected that the probability of tumor regression would increase as protein expression levels increased, and were surprised that the estimated probabilities reached a maximum around an expression level of 5, and then declined with higher levels. A logical regression model was used to relate expression 1evels to clinical outcome (indicator of tumor regression). The linear predictor in the logistic regression model included a term with a parameter θ, such that for $\theta \geq 1$ the probability of tumor regression increases with expression level, while for $\theta < 1$ the probability of tumor regression increases up to a level of 5, then decreases. From a statistical perspective the evidence in favor of $\theta < 1$ was weak with a Bayes Factor of 1.65 ('not worth a bare mention' on Jeffreys' scale of interpretation for Bayes Factors (Kass and Raftery 1995). The goal of the second study is to investigate whether this decline was a chance occurrence. If the decrease is real, then this may suggest that a higher dose is necessary at higher expression levels, leading to other experiments.

Spezzaferri (1988) presented a utility function for model discrimination which can be used in designs for testing $H_0{:}\theta \geq 1$ versus $H_1{:}\theta < 1$. Spezzaferri's criterion can also incorporate parameter estimation, but for simplicity only model discrimination is considered. The expected utility function for model discrimination can be represented as

$$U(e) = \int_{\Omega} pr(\theta < 1|Y, e)p(Y|e, H_1)\mathrm{d}Y$$

where $p(Y|e, H_1)$, is the marginal distribution of the new data under $H_1{:}\theta < 1$.

The experimental design involves selecting the total sample size N_e, as individuals with specific protein expression levels cannot be selected in advance due to costs of obtaining the results. The expected utility versus negative costs ($-\$2000 \times N$) is illustrated in **Figure 1**, and was constructed using smoothing of utilities generated using Monte Carlo experiments (Müller 1999). While analytic calculations are intractable, calculation of utilities for this model are straightforward via simulation. The marginal distribution for Y given an experiment with sample size N must incorporate averaging over different configurations of expression levels among the N subjects and the unknown parameters in the logistic regression model. Configurations of size N are generated using a multinomial distribution, with a probability vector π. The expression level distribution from the first study is used to construct a conjugate Dirichlet prior distribution for π. Data from the previous experiment is used to construct the prior distribution for θ and other parameters in the logistic model, and construct the

Figure 1 Smoothed expected utility for model discrimination vs. costs; the points indicate simulated expected utilities which exhibit Monte Carlo variation

Figure 2 Combined utility for model discrimination with a penalty for costs; the triangle indicates the combined utility at the optimal design

predictive distribution of the new data given a vector of new expression levels. For each set of stimulated data under the new study $Pr(\theta < 1|Y, e)$ is calculated, which incorporates both the old data (in the prior distribution) and the new data. For each sample size N, protein expression levels and outcomes are repeatedly generated from their predictive distributions, and the average $Pr(\theta < 1|Y, e)$ over experiments e with the same sample size N_e provides an estimate of the expected utility for e. These averages were smoothed in order to eliminate Monte Carlo variation in their estimates and are plotted in **Figure 1**.

For the above criterion, expected utility will increase with the total sample size, and as formulated the design problem has an infinite solution. Each point on the curve (**Figure 1**) is a combination of $U(e)$ and cost. Expected utility has a maximum at 1, which is obtained as N goes to infinity (and with infinite costs). The experiment which minimizes costs is given by $N = 0$, where the posterior probability that $\theta < 1$ given the data from the previous study was 0.85. The researchers want to minimize total costs, but at the same time find a sample size such that the expected utility is above 0.95 (corresponding to a Bayes factor above 3, which would provide strong evidence in favor of H_1). Combining costs and model discrimination, the combined expected utility function can be written as

$$U(e) - \lambda(\$2000 * N_c) \qquad [10]$$

where λ reflects the trade-off between for discriminating between the two hypotheses and costs of subjects. In general, it is difficult to specify these trade-offs explicitly, as the different components are often measured in different units. Verdinelli and Kadane (1992) illustrate choosing λ when there are trade-offs between two components in a utility function. If the expected utility for model discrimination is selected as 0.95, then the corresponding cost is \$421 327 (the point represented by the triangle in **Figure 1**), and λ corresponds to the negative of the slope of the curve at this point (λ=0.0001961/\$2 000). **Figure 2** shows the combined utility given by Eqn. [10] using this value of λ. The maximum (marked by the triangle) corresponds to an optimal sample size of 211. For utilities which combine more than two objectives, graphical solutions may not be feasible, but a constrained optimization approach can be used to determine the trade-off parameters (Clyde and Chaloner 1996).

Summary

Bayesian experimental design is a rapidly growing area of research, with many exciting recent developments in simulation-based design and a growing number of real applications, particularly in clinical trials. By incorporating prior information, the Bayesian approach can lead to more efficient use of resources with less costly, and more informative, designs. Utility functions can be explicitly tailored to the given problem and can address multiple objectives. Models, prior distributions, and utility functions have often been chosen to permit tractable calculations. However, with increased computing power, simulation-based methods for finding optimal designs allow for more realistic model, prior and utility specifications. Optimal designs have often been criticized because the number of support points in the design equals the number of parameters (in nonlinear Bayesian design this is not always the case), which does not permit checking the assumed model form. Model uncertainly is almost always an issue in inference, and certainly at the design stage. Bayesian model averaging has been extremely successful in accounting for model uncertainly in inference problems, and has great potential for use in Bayesian experimental design for constructing more robust designs.

Abstract

In randomized experiments designed to evaluate the relative efficacy of two or more treatments or interventions, subject noncompliance with (or nonadherence to) assigned treatment may seriously jeopardize the interpretation of results from such studies. Essentially, the noncompliant subject self-selects his or her treatment and/or treatment level, thereby disturbing the covariate balance (1995) and its associated safeguard against confounding factors that are afforded by randomized treatment assignment. In the case of educational or behavioral interventions, noncompliance may manifest itself as lowered attendance at intervention sessions or refusal of assigned (or offered) interventions. The causal interpretation of intervention effects may be seriously compromised by confounding factors introduced by subject noncompliance. Approaches to modeling causal treatment effects in light of the noncompliance problem are described using the counterfactual model for causal inference made popular by several studies.

Subject noncompliance with, or nonadherence to assigned treatment in randomized experiments designed to evaluate the relative efficacy of two or more treatments or interventions may seriously jeopardize the interpretation of results from such studies. Essentially, the noncompliant subject self-selects his or her treatment and/or treatment level, thereby disturbing the covariate balance (Rosenbaum, 1995: pp. 14–15) and accompanying safeguard against confounding factors afforded by randomization. Attributing subject outcomes to the treatments under study when subjects are noncompliant is stymied by confounding factors introduced by that noncompliance. For example, in a study to evaluate the relative efficacy of mental health interventions on the quality of life for breast cancer patients (Helgeson et al., 1999), women were asked to attend eight sessions of either an informational seminar or peer support group during the course of their adjuvant chemotherapy and/or radiation treatments. In this case, women's lowered attendance at their assigned interventions may have been related to how well they were tolerating their drug or radiation treatments, which at the same time may have affected their quality-of-life outcomes, so that the effects of the interventions are obscured.

Difficulties with Noncompliance

The complication of noncompliance necessitates the clear distinction between treatment *assignment* and treatment *exposure*. In randomized experiments with perfect compliance, these are the same; but when some subjects are noncompliant, assignment and exposure are different for those noncompliers. This distinction represents the crux of the problem induced by noncompliance: if a study is analyzed without regard to differences in assignment and exposure (e.g., using an intention-to-treat analysis) then the research question that is answered may not be the one that is posed.

Boruch (1997) takes a strong stand for analyzing studies as they are randomized (i.e., without accounting for noncompliance), since compliance behavior during a randomized trial is likely to approximate that same behavior in the general population were the interventions under study to be applied more broadly. Indeed, substantial noncompliance in itself may speak to the efficacy of assignment to the interventions under study. Nevertheless, understanding the relative efficacy of exposure to interventions and possible relationships between compliance behavior and subject outcome warrants a deeper examination of compliance.

Consideration of the statistical problems induced by subject noncompliance has taken place primarily in the field of clinical trials in cases where subjects take less of their assigned drug treatment and/or supplement their treatments with medications or activities other than the ones under study. A direct translation of the compliance problem from the medical setting to the behavioral or education setting comes from considering attendance at sessions of experimental interventions as a 'dose' or 'treatment level.' Alternatively, non-compliance with behavioral interventions might be as simple as subjects not taking advantage of an offered program, such as a family's decision to keep their child in public school even after they have been selected by lottery to attend a private school (see Barnard et al., 1999).

Regardless of the manifestation of noncompliance, questions regarding causal effects of interventions under study remain. Holland (1986) provides an extensive overview of causal inference in statistics, making use of the counterfactual model, the seeds of which date at least to Fisher (1918) and Neyman (1923), and which has been refined over several years by Rubin (1974, 1977, 1978, 1980). This model, relating exposure and outcome, is summarized here to provide a framework for illustrating the noncompliance problem and for describing methods for describing existing methods for addressing that problem (Dawid (2000) argues for causal modeling without using counterfactual outcomes, though addressing noncompliance is greatly facilitated by their use; see discussions following this article).

The Counterfactual Model

The foundation of the counterfactual model is the notion of potential outcomes, which are the collection of outcomes that would be observed for a subject if that subject were exposed to all possible treatments. The words counterfactual and potential suggest quantities that are not observed – outcomes 'counter to the fact,' or that 'might be observed.' Consider N subjects, and let T_i. denote the treatment assignment and X_i the treatment exposure for subject i. For simplicity, let T_i and X_i assume binary values, 0 and 1, representing a control and active treatment, respectively.

The specific quantities of interest for causal inference are subject outcomes under each treatment: $Y_i(0)$ is the outcome that would be observed for subject i if he or she were exposed to treatment 0, and $Y_i(1)$ is the outcome that would be observed for the same subject if he or she were instead exposed to treatment 1. Typically, only one of $Y_i(0)$ or $Y_i(1)$ is observed for each subject. The observed outcome for subject i, Y_i (or $Y_i(X_i)$), is linked to the counterfactuals via the consistency relation

$$Y_i = Y_i(1)X_i + Y_i(0)[1 - X_i] \qquad [1]$$

that is, the observed outcome *is* the potential outcome under the observed treatment exposure.

It should be noted that $Y_i(0)$ and $Y_i(1)$ are reduced from their general form as functions of the entire vector of treatment exposures via the *stable unit treatment value assumption* (*SUTVA*) of Rubin (1980). This assumption asserts that each subject's potential outcomes depend only upon his or her own treatment exposure and not those of any other subjects. In clinical trial settings, where subjects typically do not interact, SUTVA may be a reasonable assumption. In studies of behavioral or educational interventions, however, where subjects may interact with each other extensively, this assumption must be examined more carefully, and the causal conclusions that are based on it may be tenuous (Gitelman, 1999).

The potential outcomes just defined, and SUTVA, are sufficient for defining an individual causal effect (ICE). This is simply the effect, for subject i, of exposure to treatment 1 versus exposure to treatment 0

$$Y_i(1) - Y_i(0) \qquad [2]$$

Alternative individual causal effects such as the ratio of these individual potential outcomes or the difference of their logs could be considered, though the causal parameter obtained by taking the expectation of the difference in eqn [2] argues for using this simpler form. The average causal effect (ACE) is the individual causal effect averaged over the space of subjects

$$\theta = E[Y(1) - Y(0)] = E[Y(1)] - E[Y(0)] \qquad [3]$$

The probability distribution over which these expectations are taken is induced by the process by which subjects enter, or are selected for, the study.

In general, θ is nonidentifiable without further assumptions. Rubin (1978) showed, for instance, that θ is identifiable when treatment exposure is 'ignorable,' meaning that each subject's treatment exposure is stochastically independent of his or her collection of potential outcomes (this independence is expressed using the symbol $\coprod$), following Dawid (1979)

$$\{Y_i(0), Y_i(1)\} \coprod X_i \qquad [4]$$

Under randomized treatment assignment and complete compliance, treatment exposure ignorability holds, since $X_i \equiv T_i$ for all subjects i. In this case

$$\begin{aligned} \theta &= E[Y(1)] - E[Y(0)] \\ &= E[Y(1)|X = 1] - E[Y(0)|X = 0] \\ &= E[Y|X = 1] - E[Y|X = 0] \\ &= \alpha \end{aligned} \qquad [5]$$

where the second equality follows from ignorability and the third from the consistency relation in eqn [1]. α is called the apparent treatment effect, and it can be estimated by the difference in sample means of the group of subjects exposed to each treatment, perhaps appropriately scaled by a standard error estimate. Notice that α is typically identifiable regardless of treatment exposure ignorability – it is its equivalence to θ that is afforded by ignorability.

If treatments are randomly assigned, but some subjects are noncompliant, then treatment exposure is probably *not* ignorable. In that case, the apparent treatment effect is not a good estimate of the average causal effect. Specifically, there may be some characteristic of the subject (e.g., in a study comparing educational interventions, his or her academic ability) that predisposes him or her to be noncompliant with treatment assignment. This very characteristic may also be reflected in his or her potential outcomes under that treatment, and therefore his or her outcome cannot be attributed solely to the treatment in question.

One option when faced with noncompliance is to estimate the *intention-to-treat* effect, and use it as an estimate of the average causal effect. The intention-to-treat effect is given by

$$\alpha_{\text{itt}} = E[Y|T = 1] - E[Y|T = 0] \qquad [6]$$

which can be estimated by the difference in sample means of the two treatment groups. This effect explores the relationship between assignment and outcome. Alternatives to this approach that seek to illuminate the relationship between exposure and outcome are described next.

Simple Noncompliance

In the case of binary treatment assignment and binary treatment exposure, noncompliance with treatment assignment manifests as 'treatment switching.' That is, a subject assigned to the active treatment is noncompliant if he or she switches to the inactive treatment (for instance by not taking the treatment at all). Similarly, a subject assigned to the control treatment is noncompliant by switching to the active treatment. This is essentially the situation described in Barnard et al. (1999), wherein families participated in a lottery to receive funding and other support for private school attendance. Some families, even though they 'won' the lottery, decided to keep their children in public schools – hence, these families are the 'noncompliers.'

Modification of the Counterfactual Model

The counterfactual outcomes described previously depend upon treatment exposure only, whereas to account for noncompliance they must be altered to depend also on treatment assignment. Following Angrist et al. (1996), let $X_i(0)$ and $X_i(1)$ denote potential or counterfactual exposures for subject i; these are the treatments subject i would be exposed to (i.e., based on his or her compliance behavior) under assignment to treatments 0 and 1, respectively. Let $Y_i(T_i, X_i(T_i))$ denote the potential outcome of subject i, under treatment assignment T_i and exposure $X_i(T_i)$. Expression of both the potential exposures and potential outcomes again rely on Rubin's SUTVA. In the binary assignment and binary exposure case, each subject has four potential outcomes, one for each assignment/exposure pair

$$\{Y_i(0,0), Y_i(0,1), Y_i(1,0), Y_i(1,1)\} \quad [7]$$

For instance, $Y_i(1, 0)$ is the outcome subject i would experience had he or she been assigned to the active treatment and been noncompliant with that treatment, thereby receiving the control treatment.

As in the case of the simpler potential outcomes $Y_i(0)$ and $Y_i(1)$, the outcomes in eqn [7] are related to the observed outcome via a consistency relation

$$Y_i = \sum_{t=0}^{1} \sum_{x=0}^{1} Y_i(t,x) I_{\{T_i = t, X_i = x\}} \quad [8]$$

where $I_{\{\cdot\}}$ is the indicator function. As before, the observed outcome is the potential outcome that corresponds to the observed treatment assignment/exposure pair. Non-identifiability is more drastic in this setting, however, as there are now four counterfactual outcomes to consider for each subject instead of just two.

The causal parameters of interest are the expected values (with expectations taking over the space of subjects) of the potential outcomes in eqn [7]; namely

$$E[Y(0,0)], \quad E[Y(0,1)], \quad E[Y(1,0)], \quad \text{and} \quad E[Y(1,1)]$$

With noncompliance, exposure is not ignorable, and so it is not necessarily the case that $E[Y(0, 0)]$ equals $E[Y(1, 0)]$ or that $E[Y(0, 1)]$ equals $E[Y(1, 1)]$. That is, the average subject outcome of a noncompliant subject assigned to the treatment arm will not, in general, be the same as that of a *compliant* subject assigned to the control arm. Methods to address this complication are described next.

Bounds for ACE Using an Instrumental Variable

A variable T is an *instrumental variable* if the distribution of another variable, Y, depends on T only through a third variable, X. Instrumental variables have been popularized in the econometrics literature (*see* Instrumental Variables in Statistics and Econometrics); they have been used to address noncompliance in other settings (e.g., Angrist et al., 1996). Ideally, T and X should be correlated, and T and Y uncorrelated conditionally on X. Then T can be used as a surrogate or *instrument* for X. An instrumental variable, then, is a variable that is partly defined by a conditional independence relationship, known as the *exclusion restriction*, or *instrumental variable assumption*

$$T \coprod Y|X \quad [9]$$

and partly by the required correlation between T and X. Angrist et al. (1996) translate this assumption into the language of potential outcomes, using assignment as an instrument for exposure

$$Y_i(T_i, X_i(T_i)) = Y_i[X_i(T_i)] \quad [10]$$

that is, a subject's potential outcomes do not depend on the treatment assignment directly, but only through that assignment's effect on the treatment exposure. Angrist et al. (1996) show the equivalence of the counterfactual and structural (or simultaneous) equation models (*see* Simultaneous Equation Estimation: Overview).

The instrumental variable assumption in eqn [10] has the effect of reducing the number of potential outcomes from four, as in eqn [7] to two, simply $Y_i(0)$ and $Y_i(1)$. For each subject, however, each of $Y_i(0)$ and $Y_i(1)$ can be observed in one of two ways, either by the subject's compliance with assigned treatment or their noncompliance with the opposing treatment. By using assignment as an instrument for exposure the average causal effect, θ can be bounded by taking minimums or maximums over these two ways of observing each treatment exposure (of course, these bounds also depend upon the responses having bounded expectations). Balke and Pearl (1994) produce the tightest possible bounds for θ (under binary assignment, binary exposure, and binary outcome) using the instrumental variable assumption and linear programming results.

Angrist et al. (1996) use the instrumental variable assumption, combined with a monotonicity assumption, to estimate θ rather than bound it. This monotonicity assumption applies to the counterfactual exposures – it is assumed that a subject will only be noncompliant by switching from the active treatment to the inactive control, but not vice versa, whereby $Y_i(1, 0)$ is eliminated from the collection in eqn [7]. Because it relates exposure under an active treatment to that under a control treatment, this monotonicity assumption only is applicable in trials that compare an active treatment (or treatments) to a control.

Noncompliance as Underdosing

A more complicated noncompliance situation occurs when noncompliant subjects take a lower-than-intended dose of their assigned treatment (or attend fewer-than-intended sessions of their assigned intervention), rather than switching between treatments. For simplicity, treatment assignment remains binary in this discussion. The counterfactual exposures, $X_i(0)$ and $X_i(1)$, now take categorical or even continuous values, however, and there is no switching between treatments except perhaps in the case of a subject taking a zero dose of an active treatment. In a randomized dose-response experiment, subjects are randomly assigned to different doses of a treatment (i.e., dose is ignorable); but with noncompliance the subjects *choose* those doses (i.e., compliance levels), and

so the resulting treatment outcomes cannot be attributed to dose or compliance levels alone.

In a direct extension of the simple compliance case discussed previously, Goetghebeur and Molenberghs (1996) model counterfactual compliance-response curves (similar to dose-response curves) for categorical exposure levels and binary outcomes, Their model relies on a different monotonicity assumption (this one asserts that increased compliance cannot lead to decreased probability of a successful outcome); an instrumental variable type of assumption and a constant global odds ratio assumption. A subsequent contribution, Goetghebeur et al. (1998), relaxes this last assumption somewhat. An essential difficulty with these models, however, is that due to the need for modeling counterfactual (i.e., unobservable) outcomes, rather strong, untestable assumptions are needed. For example, the constant global odds ratio assumption is untestable, and it dictates an artificial relationship between the counterfactual compliance-response curves.

Efron and Feldman (1991) take the approach of modeling compliance behavior as a fixed attribute of the subject, rather than as a response to treatment assignment. As a fixed attribute, each subject's compliance behavior remains the same, regardless of the treatment to which he or she is assigned – this eliminates the problem of having to address counterfactual exposure levels. Compliance-response curves are estimated with this approach, and with additional modeling assumptions (e.g., linearity of the dose-response relationship), portions of the 'true' dose-response curves are recovered. Again, the true dose-response curves can be fully estimated only if dose level is ignorable.

Robins (1994) explores the slightly different setting of sequential randomized trials, in which subjects are assigned to treatment regimes in series, interspersed with assessment of their medical condition. In this article it is assumed that, conditional on all observable covariates, the treatment exposure regime is ignorable.

Addressing Noncompliance in Practice

When subjects are noncompliant with assignment to experimental interventions, a study loses the solid footing afforded by randomized treatment assignments. The essential question of interest regarding the effect of exposure to interventions is now compromised by the subject's selection of their intervention and/or intervention level. The counterfactual model provides a foundation for examining the relationship between exposure and outcome, though careful consideration of the assumptions of both that model and the additional modeling components needed for identifying causal parameters of interest are crucial and may depend upon the type of study.

When faced with compliance problems, or the possibility of compliance problems, the researcher may be best served by careful planning of intervention delivery with an eye toward averting attendance problems or other lapses in the integrity of the intended treatment (Meyer and Fienberg, 1992). Furthermore, by collecting as many relevant covariates as possible, differential, subject-selected treatment exposure can be alleviated, in part by adjusting for these covariates using, for example, propensity score matching (Rosenbaum and Rubin, 1983). If sufficient subject covariates are observed, it may be reasonable to assume that treatment exposure level is ignorable conditional on these covariates, whereby the causal parameters of interest can be identified. For compliance problems that cannot be addressed a priori, however, the bounding (e.g., Balke and Pearl, 1994) and modeling (e.g., Angrist et al., 1996; Barnard et al., 1999) methods described herein provide useful options.

Experimental Design: Large-Scale Social Experimentation

This article is a revision of the previous edition article by C.N. Morris, C.W.F. Chiu, volume 8, pp. 5086–5090, © 2001, Elsevier Ltd.

Abstract

Large-scale social experiments became scientifically feasible in the 1960s, and the US government began funding them to obtain better information for policymakers. The rate of new experiments has risen steadily since then, although the newer experiments tend to be smaller and more focused. This article reviews some of the advantages, disadvantages, and design issues that accompany large-scale, long-term social experimentation.

An experiment is a deliberately planned process to collect data that enable causal inferences and legitimize treatment comparisons. Random assignments of subjects to treatments (including control groups) allow statistically significant differences among treatment outcomes to be attributed solely to the treatment differences. Without strong additional assumptions, observational studies and quasi-experiments cannot justify drawing causal inferences, because only experiments, by definition, assign the treatments randomly (*see* Interrupted Time Series Quasi-Experimental Designs; Experimental Design: Randomization and Social Experiments; Experimental Design: Compliance).

Public welfare relies on experiments for many purposes, including to approve medicines, medical procedures, new foods, and product reliability. Large-scale social experiments differ from most of these experiments, even from many that involve human subjects, in that the treatments in social experiments are social programs, the subjects are humans, and the responses measure outcomes for these people (or families) as they make decisions under different possible programs.

Large-scale public policy experiments in the United States generally are considered to have started with the New Jersey Negative Income Tax Experiment (NJ–NIT) 1968. Orr (1999) puts the number of social experiments (not all large scale) launched per decade in the US at six in the 1960s, at 49 and 84 in the next two decades, and then at 56 for 1991–95.

These experiments were fielded to gather scientific information so that policymakers could know as accurately as possible the costs and benefits of possible social programs. Most social experiments have been initiated and funded by agencies (national, state, or at other political levels) concerned with the welfare of large populations. While these large experiments have been costly and time-consuming, they have found sponsors partly because their costs were dwarfed by the costs of actual programs.

Some Examples

Much has been written about social experiments. Greenberg and Shroder (2004) summarize the duration, cost, treatments, measured outcomes, sample sizes, design, funding sources, developers, evaluators, and results of over 100 of them. Orr (1999), Fienberg et al. (1985), and others in the references here, review some of the main studies and list further sources. This article describes several of the better-known public policy social experiments, each of which monitored human subjects for several years as they made personal or family economic decisions while being eligible for benefits provided by an experimental policy to which they were randomly assigned.

The New Jersey Negative Income Tax Experiment

The NJ–NIT experiment (Fienberg et al., 1985; Greenberg and Shroder, 2004; Orr, 1999; Hausman and Wise, 1985) was inspired by the thesis of Ross (1966) while she was a PhD student in economics at MIT. Ross argued that only a social experiment could resolve disputes over how work patterns of the poor might change if the government were to adopt a Negative Income Tax (NIT) program to supplement their incomes. The Office of Economic Opportunity in the Department of Health, Education, and Welfare (HEW) funded the initial Income Maintenance Experiment (IME) to begin in 1968. Mathematica Policy Research, commissioned to design and field it, randomized a total of 725 experimental households into nine treatment groups, and another 632 households into a control group, with welfare and near-welfare households in four New Jersey cities being enrolled for 3 years each. The nine experimental treatments in this response surface design involved two main variables: one providing a range of income guarantees and the other providing a range of tax rate reductions to families as incentives to earn additional income. The NJ–NIT objectives were to estimate, mainly via regression analyses, how work hours, rates of high-school graduation, and other outcomes depended on these factors.

Difficulties encountered in the NJ–IME included significant nonstationary participant behavior at the outset caused by participants needing time to become familiar with their program incentives, and toward the end caused by some gaming behaviors. The NIT design deliberately correlated the random treatment assignments with family incomes in order to reduce experimental costs. That dangerous strategy complicated the analyses and risked compromising the experiment's randomization. Other design concerns included differences (lack of balance) between treatment and control participants in their initial income reporting, and use of total income as

an eligibility criterion at enrollment with a resulting underrepresentation of working wives.

The Health Insurance Experiment

The need for a health insurance experiment was recognized during the Nixon administration when for the first time the government was considering possible forms of a national health insurance program. Congressional leaders held widely divergent views about possible costs of a national program, and especially about the elasticity of demand for health care. If demand were completely inelastic, previously insured individuals would continue to purchase medical services at the same rate. That would make government sponsorship more affordable. While no experiment could provide all needed information, policymakers funded the health insurance experiment (HIE) because it would narrow the range of disagreements, and help avoid disastrous errors in a national program.

The HIE was fielded in 1974 as the income maintenance experiments wound down. The Office of Economic Opportunity, and later HEW, asked the Rand Corporation to design and conduct the HIE, ultimately detailed in *Free for All* (Newhouse, 1993) by its principal investigator.

The HIE was designed to assess the demand for health care and many other questions, including whether health benefits might derive from a national health insurance program. Nearly 3000 families, each for 3–5 years, were randomized to one of 14 insurance plans, including an HMO group. Insurance plans had two main dimensions, with varying family-level coinsurance rates, and with varying deductible limits (after reaching the limits families were exempted from any further expenses for the years remaining). Anticipating that the world might differ considerably after the results of an 8-year experiment became available, the HIE treatments included no particular proposal, but instead were chosen to provide a range of rates and benefits that could be used reliably to extrapolate HIE results to future legislative proposals.

Demand in the HIE was ultimately found to be elastic. Perhaps primary among HIE findings have been the elasticity estimates that legislators continued to use for years when comparing the costs of new health insurance proposals (Newhouse, 1993; Orr, 1999).

JOBSTART, a Demonstration

The rate of new social experiments continued to increase as the technology for doing them matures, and as new research groups and firms develop the skills to design, conduct, and analyze them. However, the newer experiments have tended to be smaller and more focused than the first ones, many having been designed to demonstrate the effectiveness of an existing program, and to identify areas for improvement. These 'demonstration' experiments are simpler to field than those, like the IME and the HIE, that were designed to provide information on a wide range of unspecified programs.

Perhaps politicians are partial to demonstrations because of their lower costs and because they focus on concrete legislation. Demonstration experiments cost less because some of the participant funding comes through an existing program's benefits, and because focus is exclusively on one treatment and a control group. A complication is that control group subjects, if matched to treatment subjects, will be eligible for the same program benefits and so must be allowed to access them. One way to counter this is to have the treatment be an encouragement for eligible subjects to take advantage of an underused program.

JOBSTART was a demonstration experiment to evaluate the Job Training Partnership Act (JTPA) of 1982 (Greenberg and Shroder, 2004; Cave et al., 1993). Sponsored jointly by the US Department of Labor and by several private foundations, JOBSTART was designed and evaluated by Manpower Demonstration Research Center (MDRC) between 1985 and 1992, and administered by the Local Service Delivery Areas in 13 geographically disparate US sites. Subjects were randomized into treatment and control groups, with about 1150 subjects in each. All subjects were JTPA eligible (a national program), being economically disadvantaged high-school dropouts aged between 17 and 21 years, and all were poor readers. Treatment interventions included two summers of vocational and educational training, support services, job placement assistance, and incentive payments. Subjects were monitored for 4 years.

JOBSTART found that the treatment group had a dramatically higher rate of high-school completion. Women who had no children before the demonstration, but who gave birth afterward, were less likely to receive Aid to Families with Dependent Children (AFDC) payments. The opposite result was found for women who started with children. No major long-term differences were found for employment, earnings, or welfare measures.

The Housing Assistance Supply Experiment (HASE)

Economic theory predicts an elastic supply response to increased demand, so that benefits received by individuals do not necessarily rise in proportion to the dollars provided. Even so, almost all large-scale social experiments have measured demand only, mainly because a supply response is extremely difficult to produce in an experiment. The Housing Assistance Supply Experiment (HASE) is a notable exception (Lowry, 1983). While Housing Allowance Demand Experiments had been fielded to evaluate new housing policies (Bradbury and Downs, 1981), evaluating the supply response to alternative housing programs requires a long-term saturation experiment in which all eligible members of an entire community participate in an experimental program. A supply experiment takes longer because the supply side (the construction industry in this case) needs adequate time to respond to any new demand, generally much longer than individuals need to respond to new opportunities.

The Department of Housing and Urban Development sponsored HASE to learn how the supply side would respond if individuals and families received increased government assistance for making home improvements. HASE ran from 1972 to 1982 in Green Bay, Wisconsin, and in South Bend, Indiana, selected as two small, stable communities in which a meaningful supply response might be stimulated. Long-term benefits were guaranteed to all eligible families for 15 years, well beyond the length of the experiment, to give the construction

community sufficient incentive to relocate workers and businesses into these regions.

Supply experiments are extremely ambitious, but the questions they address are crucial.

Alternatives to Social Experiments

Less expensive alternatives must be considered before undertaking a social experiment. These include expert (and nonexpert) opinions, theoretical models, surveys, observational studies, quasi-experiments (*see* Interrupted Time Series Quasi-Experimental Designs; Experimental Design: Compliance), and, if they exist, appropriate 'natural experiments.' Because these alternatives usually are cheaper, faster, and easier than an experiment, they will be preferred whenever they can provide valid predictions. Even if they cannot produce valid predictions, their consideration is vital as a precursor to designing an efficient social experiment.

These alternatives all have drawbacks. Expert opinions and theoretical models are no better than the experts or models. While surveys can sample randomly from a target population, they cannot assign treatments randomly, and surveyed subjects rarely would know how they would respond to a hypothetical future program. Nonexperimental data, quasi-experiments, and observational studies (both being nonrandomized studies) might be used to extrapolate from data on existing programs to predict outcomes of untried programs. Such predictions, however, are especially unreliable for major program changes, and self-selection in such data may bias results. Natural experiments might occur if a comparable country or region adopts a policy similar to one under consideration, but such often do not exist, and when one does occur, results still must be extrapolated to another country or population.

As none of these alternatives has randomly assigned treatments, selection bias will be present and causal inferences will be suspect. Drivers who use seat belts have lower traffic fatality rates, but those rates are confounded with the same drivers being generally safer drivers. Similarly, individuals who choose health insurance plans with less generous coinsurance rates generally consume fewer health services. Is that only because disproportionately many of them, knowing they are healthier, choose less generous insurance plans that they pay for? If so, their behavior in a future health insurance program that includes the entire population will not be reliably predictable from their past utilizations. A health insurance experiment (being randomized) offers an alternative option to using observational data for predicting the costs of proposed national health insurance programs.

Risks of Social Experiments

Being costly and time-consuming, social experiments have been used sparingly. They might not provide useful information for many years, risking their being irrelevant. Human subjects can refuse to enroll, and enrollees can drop out before completion. If that happens with regularity, the desired randomization fails, and so the experiment fails (*see* Nonsampling Errors).

If large experiments become too visible, their subjects may feel that the situation is artificial and act differently than they would when covered by a national program.

Drastic political, social, legislative, or economic changes can occur during an experiment and potentially invalidate it. However, a control group can be protective in such situations, to the extent that the shock affects all treatments and controls equally. Orr (1999), who as a government economist helped spawn and plan several early public policy experiments, reviews such concerns about social experiments, and he discusses how experiments can protect themselves. Besides the issues mentioned here, he discusses whether and how experiments have affected policy, their credibility, time considerations, communication issues, their generalizability, relevance of their results, the policy environment, and policy links.

Design Issues

Those who design social experiments make numerous crucial choices. They must choose treatments that span the policies that are likely to be considered without wasting too much of the budget by picking an overly large range that provides too little information on the policies that ultimately matter. But, how many sites are needed? Too many sites are difficult to manage, and for a fixed budget, increased management costs that must be paid for by decreased sample sizes. Too few sites restrict generalizability. Should sites be chosen randomly? Probably not if the number of sites must be kept small, because then randomization provides little basis for inference.

More subjects are better, but too many subjects make an experiment unfeasibly expensive. Without strong reasons to do otherwise, it helps to keep the percentage of subjects allocated to each treatment the same in every experimental site. Balanced samples (balance refers to matching the key characteristics of the sample across sites and treatments) have various optimal properties in experimental design, and they enjoy considerable face validity (Morris and Hill, 2000).

Enrollment participations must continue long enough for individuals to learn how to take advantage of experimental programs (and so to reach steady state), and perhaps to discount (or adjust for) the times at the beginning and/or the end of the experiment when subjects may act differently than they would in a continuing government program. However, overly long enrollments waste time and budgets because early results are better for policy, and also, when there are positive correlations within individuals, because for estimating mean responses, one individual for more years provides less information per year than does a larger number of individuals, each for fewer years, assuming an equivalent number of person-years. These transitory issues may make it necessary to field a longer experiment, or at least to guarantee treatment benefits to participants beyond the actual measurement period.

Decisions about what data to collect, about the design of questionnaires, and about how much and how frequently to interview subjects can be as crucial as other statistical design decisions. Interviewing subjects too often or too intensively (respondent burden) risks overstimulation, causing them to become overly aware of participating in an experiment and

inducing artificial behavior, termed 'Hawthorne effects.' Respondent burden can cause dropouts, careless responses, and selective nonresponse. Interviewing subjects too infrequently sacrifices potentially important data, so a balance must be struck. Experimenters can usefully gain a better understanding of respondent burden by subjecting themselves to the same interviewing processes that experimental subjects face.

While large-scale social experiments encounter difficulties beyond those of smaller experiments, they will have greater financial resources to deal with them. Some potential difficulties that concerned HIE designers included creating Hawthorne effects by frequent interviewing; activating participants by obtaining a medical screening examination at enrollment; stimulating health expenditures by having to pay participation incentives to families; and not being sure of the best time horizon (Newhouse et al., 1979). The HIE budget allowed for four (balanced) 'subexperiments' within the main experiment to measure these effects. In one subexperiment, half of the HIE subjects were chosen at random for weekly interviews, and half for biweekly. Similarly, 60% of the HIE subjects were randomly selected for initial screening exams, and the rest not; and 70% were randomly assigned for 3-year enrollments, and the other 30% for 5 years. This allowed testing for these effects and, if found, adjusting for them.

Further Reading

Orr (1999) provides an overview and first-hand examples of the design and implementation of social experiments. Greenberg and Shroder (2004) summarize 143 completed social experiments in the United States, and 75 others that were ongoing at the time of their publication. Each summary describes the target population, policies tested, experimental design, sites, findings, sources of further information, and public access to the data. Campbell's fundamental work in social experimentation is summarized in Campbell and Russo (1999). Boruch (1997) provides reference material on randomization in field experiments, and Neuberg (1989) discusses anomalies of social control experimentation.

Abstract

Experimental design is the art of devising an experimental plan that maximizes the information that can be obtained on the effects of stimuli (treatments) presented to subjects. The article discusses basic features of good design, including comparison of treatments, randomization, avoidance of bias, and reduction of variability. Designs are classified as between-subjects designs, where subjects are assigned one treatment each, and within-subjects designs, where subjects are assigned sequences of treatments. Between-subjects designs include completely randomized designs, where subjects are assigned completely at random to treatments, and matched designs or block designs, where subjects are divided into groups (blocks) of like subjects and random assignment is done within each block separately. Within-subjects designs include crossover designs and split-plot designs. In these, there can be problems of carryover effects, where each measurement may depend not only upon the treatment given in that time period but also on the preceding treatment(s). Counterbalanced Latin squares, which have every treatment preceding every other treatment the same number of times, can be used to isolate treatment effects from carryover effects.

Many scientific discoveries are made by observing how a change in a stimulus that is presented to a subject or object affects the response (measurement) given by that subject or object. In an experiment, the investigator has direct control over which stimuli are presented to which subjects in which time periods. This control, when exercised correctly, enables the investigator to deduce a 'cause and effect' relationship, that is, the investigator can deduce that a given change in a stimulus causes a given change in the measured response. The plan of how an experiment is to proceed is called the 'design of the experiment.' The art of experimental design is the art of devising an experimental plan that maximizes the information that can be obtained on the effects of the stimuli.

Terminology

Experimentation is used in almost every branch of science, with the result that the terminology used in experimental design is not quite standardized. For example, in some fields, the subject or object which is to be presented with a stimulus and then to be measured is called a 'unit' or an 'experimental unit.' The stimulus, itself, may be called the 'treatment' or the 'level of a factor' or the 'level of an independent variable.' In factorial experiments, where a subject is presented with a combination of different types of stimuli (such as a particular light intensity together with a particular noise level), the combination may be called a 'treatment combination' but, for simplicity, the term 'treatment' may be taken to mean either a single stimulus or a combination of stimuli, depending on the context.

In some experiments, measurements are made on each subject over several time periods. These are known as 'repeated measurements.' The terminology concerning the associated designs again differs among disciplines. The term 'repeated measurements design' may refer solely to a design involving repeated measurements on a subject to whom a single treatment has been administered or it may include designs in which the treatment is changed before each measurement. The latter type of design is also known as a 'within-subjects design' or a 'block design' or a 'crossover design.' All of these designs are grouped under the heading of 'split-plot designs' by some authors, while others reserve this last term for a design with two types of treatment, one of which is held constant throughout the repeated measurements on a subject and the other of which changes before each measurement (see Section Split-Plot Designs).

The Purpose of Experimental Design

The pioneer in statistical experimental design was Sir R.A. Fisher (Fisher, 1951), who was concerned with maximizing the amount of information about agricultural crop production. In the social and behavioral sciences, the questions of scientific interest are very different, but the art of good experimental design is similar.

Every experiment has a budget (time and money) and a limit as to the number of subjects that can be recruited. Also, every experiment has inherent variability: subjects differ from one another in fundamental ways, technicians differ in how they read measuring instruments, subjects and instrument readings vary over time, and so on. Variability translates into uncertainty and uncertainty reduces the amount of useful information. Information gained from an experiment may be viewed either from a sampling perspective or from a Bayesian perspective. In the former, hypothesis tests and confidence intervals are generally used, and the most informative experimental designs yield the most powerful tests and the shortest intervals, while producing unbiased results. For a Bayesian analysis, the most informative designs are those that maximize the expected utility.

The purpose of designing an experiment is (1) to maximize the amount of information that can be gained within a given budget or (2) to minimize the budget required to obtain a given amount of information. Maximizing information is done by controlling and reducing the effect of extraneous

variables and by removing confounding variables and bias, as described in Sections Control of Extraneous and Confounding Variables and Removal of Bias.

Features of Good Design

Comparison

Experiments, by their nature, tend to be comparative. Questions of interest tend to be of the type 'does this treatment elicit a "better" response than that treatment?' and, if so, 'how much better?' Even if a single treatment appears to be the only one of interest, information about its effect on a subject is usually of no value without a comparison with other treatments. For instance, Moore and McCabe (1999: Chapter 3) cite an example of a medical study that showed a gastric freezing technique to be a good treatment for ulcer pain, but in later comparative experiments it was shown that the pain relief using freezing was no better than the relief achieved using the same technique but with no freezing solution. Apparently, the pain relief was due to nothing more than doctors showing concern for their patients (a placebo effect) and the freezing technique was abandoned. A good design for evaluating the effect of a single treatment will, therefore, always include a second treatment, called a control or control treatment, for comparison purposes. In some experiments, the control is the treatment in current use, and in other experiments it is the 'absence of a stimulus.' An experiment with more than one treatment needs no control since the experimental treatments can be compared among themselves. Nevertheless, a control can often add extra information. For example, in an experiment on how different types of background music (such as 'classical,' 'rock,' 'rap,' etc.) affect the time taken to learn a new task, a control treatment might be the absence of background music.

Control of Extraneous and Confounding Variables

A good experimental design allows a particular set of stimuli to be compared with each other with high accuracy. Therefore, any other variable (or factor) that causes the experimental measurements to vary at best reduces the efficiency of the experiment and at worst completely masks the true effect being investigated. For example, in an experiment to investigate the effect of employing different types of memory aid in memorization, the IQ of the subjects may play an important role. The variability of IQ of subjects in the experiment would then contribute to the variability in the measured memorization scores. One way of controlling the effect of such an extraneous variable is to hold the variable fixed during the experiment. For instance, IQ could be held more or less fixed by using as subjects only people with a tested IQ within a certain range. Although it reduces variability and avoids masking the effects of the memory aids, this strategy limits the applicability of the conclusions of the experiment since the results would apply only to the people in the population with IQ within this range. A preferable method of controlling extraneous variability is to use a matched design (see below).

An extraneous variable whose effect is completely muddled with that of the factor(s) of interest is called a confounding variable. In the above example, if all the subjects with high IQ were to be tested using the first memory aid and all those with low IQ were to be tested using the second, then, if high IQ is correlated with memorization ability, the first memory aid will inevitably appear to be the better one, regardless of its true merits.

The masking effect of a confounding variable can be reduced by randomization. The simplest form of randomization leads to a 'completely randomized design' (see Section Completely Randomized Designs); subjects are recruited from the general public as randomly as is possible (see Section Selection of Subjects) and then assigned to the stimuli at random in such a way that every subject has the same chance of being assigned to any one of the stimuli. In such a design, it is likely, although not guaranteed, that each stimulus will receive roughly the same distribution of values of the extraneous variable. If a completely randomized design is used in the above example, the memory aids should receive roughly similar ranges of subject IQs.

In all experiments there are confounding variables that have small effects, which are ignored by the experimenter, and confounding variables that are accidentally overlooked. The use of randomization helps to spread out the effects of these variables so that the response given to any one stimulus is less likely to be inflated upward or downward due to extraneous factors. For a discussion of random assignment using a random number table or a computer random number generator, see, for example, Dean and Voss (1999: Chapters 1 and 3).

A more foolproof method of ensuring similar distributions of IQ levels for each memory aid in the above example is to divide the subjects into groups so that subjects within the same group have similar IQs, and then to make the random assignment of subjects to stimuli within each group separately. The division into groups provides the control necessary for removing the variability and masking due to the extraneous IQ variable, while maintaining the applicability to the general population. This type of design is called a 'matched design' or 'block design' (see Section Matched Pairs and Block Designs). Matched designs and completely randomized design are examples of 'between-subjects designs' (see Section Between-Subjects Designs).

A further possibility is to measure each subject under a sequence of different treatments – a 'crossover design' or 'within-subjects design' (see Section Within-Subject Designs). The use of such a design in the above example would completely control the extraneous variable since it would ensure that the distribution of IQs assigned to each memory aid is identical. However, new extraneous variables have now been introduced such as fatigue on the part of the subject over the course of the experiment. If the effects of the new extraneous variables are likely to be small, they can be ignored, but if they are large, then the variables should be controlled by making sure that subjects are assigned the memory aids in different orders. The orders can be assigned at random for each subject separately – a 'block design,' or by deliberately making sure that each stimulus is viewed by the same number of subjects in each time period – a 'Latin square design.'

Removal of Bias

Since each experiment is run with a particular purpose in mind, experimenters tend to have built-in, although perhaps subconscious, biases toward or against certain treatments. A random

assignment of subjects to treatments and a random ordering of observations ensure that experimenter bias cannot consciously or unconsciously favor one treatment above another.

Subjects' own biases toward the treatments can affect their responses. It may or may not be possible or ethical to conceal the true nature of the experiment from the subjects. It may be possible, however, to mask from both the subjects and the person(s) running the experiment which of the stimuli is the experimental treatment(s) and which is the control (a 'double-blind experiment'). Leach (1991: Section 24, Appendix 1) discusses ethical issues of concealing information from subjects and lists the guidelines published by the British Psychological Society. Kirk (1982: Section 1.5) gives references to ethical guidelines put out by the American Psychological Association, the American Sociological Association, and other bodies.

Planning an Experiment

Guides to planning experiments can be found in many texts, for example, Myers (1979: Chapter 1), Cox (1958), Dean and Voss (1999: Chapter 2), and Leach (1991: Sections 5–9). A protocol, which gives in great detail, step-by-step, how the experiment is to proceed, is usually prepared well in advance. The protocol includes details about subject selection, measurement and data collection methods, preparation of materials, preparation of subjects, and a draft statistical analysis.

A pilot experiment in which a small number of observations are collected is often run early in the planning stage. Although these observations will usually be thrown away when the main experiment commences, the pilot experiment gives an opportunity to check that the experimental procedure will work as planned and that the required analyses are possible. It also gives indications of unexpected important confounding variables and the likely accuracy of the results. It allows problems to be detected and corrected before they arise in the main experiment.

Selection of Subjects

Ideally, the subjects taking part in the experiment are selected at random from the population to which the conclusions of the experiment will be applied (the 'target population'). Since this is not always possible, the experimenter may be forced to use volunteers who will inevitably come from a subset of the population. The results of the experiment may or may not then apply to the entire target population.

The number of subjects required to achieve the goals of powerful hypothesis tests and short confidence intervals, or of maximum expected utility, can be calculated using statistical formulae. The required number of subjects depends upon the design selected for the experiment, on the comparisons of interest, and on the variability of the responses of subjects when assigned the same treatment under identical experimental conditions. In general, 'between-subjects designs' require many more subjects than 'within-subjects designs.' Between-subjects designs are used in fields where subjects can be assigned only a single treatment (as in the evaluation of different teaching methods) and/or where subjects are sufficiently plentiful to offset the subject-to-subject variability. Within-subjects designs are preferred in fields where subjects are scarce or highly variable.

The length of the sequence of treatments that can be presented to any one subject depends upon the nature of the experiment. For example, in experimentation involving multiple visits to a laboratory, subject tolerance can be as low as two or three visits. In experiments in which treatments can be changed rapidly with no long-term effect on the subject, a much longer sequence of treatments can be used, requiring fewer subjects in total. There are exceptional circumstances in which an experiment is conducted on a single subject (see Wilson, 1995; Kratochwill and Levin, 1992), but such experiments cannot give conclusive information about the population as a whole and are not used in standard experimentation.

Models and Analysis

The model links the dependent (response) variable(s) to all of the factors (independent variables) that could influence the response, such as the various stimuli, the subjects, time periods, extraneous variables that were used in determining the design, and other important variables that can be taken into account only during the analysis (called 'concomitant variables' or 'covariates': see, e.g., Maxwell and Delaney, 1990: Chapter 9). All extraneous variables that were ignored in the design are grouped together in a single 'error variable.' A measurement on a subject during a time period before the experiment begins is called a 'baseline measurement' and can be used to increase the accuracy of the results (see, e.g., Jones and Kenward, 1989: Chapter 2, Section 4.4; Cotton, 1998: Chapters 9, 10).

If the distributions of the error variables are identical and approximately normal, then standard analysis of variance techniques can be used. Designs in which treatments are assigned the same numbers of subjects and the same numbers of time periods are the easiest to analyze and interpret. They are also the least sensitive to assumptions about normality of the error distributions and equal variances. When the errors do not follow a normal distribution, other types of analysis are needed such as analysis of generalized linear models and categorical data analysis (e.g., see Ratkowski et al., 1993: Chapter 7; Jones and Kenward, 1989: Chapter 3; Crowder and Hand, 1990: Chapter 8).

Repeated measurements on a subject under a particular treatment may require a time series or regression analysis (see Crowder and Hand, 1990). Bayesian techniques in analyzing crossover designs are mentioned by Jones and Kenward (1989: pp. 80, 235). In the case of correlated responses per subject, multivariate analysis is used for normally distributed errors (see, e.g., Winer et al., 1991: Chapter 4; Johnson and Wichern, 1992; Maxwell and Delaney, 1990: Chapters 13, 14; Crowder and Hand, 1990: Chapter 4; Jones and Kenward, 1989: Chapter 7; Myers, 1979: Chapter 18).

Between-Subjects Designs

Completely Randomized Designs

In a completely randomized design, each subject is assigned to just one treatment. The assignment is done completely at random so that each subject has exactly the same chance of

being assigned to each possible treatment (stimulus or combination of stimuli). Often a restriction is applied so that each stimulus receives the same number of subjects.

Completely randomized designs are simple to use and analyze. They are most suited to situations where subjects are plentiful, where subjects' responses would not be too variable if they were all given the same stimulus under the same experimental conditions, and where experimental conditions can be held constant throughout the experiment.

If there are extraneous variables that add variation to the responses and that can be measured during the experiment (such as age or IQ), their effects can be removed during the analysis (analysis of covariance) (e.g., Winer et al., 1991: Chapter 10). However, where it is possible for the extraneous variables to become confounding variables in an unfortunate randomization, a matched pairs design, block design, or within-subjects design would be preferred (see Sections Matched Pairs and Block Designs and Within-Subject Designs).

As in all designs, it is possible to take repeated measurements in completely randomized designs. Each subject is measured for some number of time intervals after administration of the single treatment. Cotton (1998) calls such a design a 'multigroup split-plot design.'

Matched Pairs and Block Designs

If there are just two treatments of interest, the variability in the responses (observations) due to differences in the subjects themselves can be reduced by pairing the subjects so that, within each pair, the subjects are as alike as possible. For each pair separately, the two subjects are assigned at random to the two treatments (a matched pairs design).

When there are t treatments with $t > 2$, the subjects are matched into groups (or blocks) of size t, and within each group the subjects are assigned at random to the t treatments. This type of design is usually known as a 'randomized block design.'

Block designs are also appropriate when the extraneous variation is due to variables unrelated to the subjects. Experimental conditions cannot always be held constant throughout the experiment, as for example, changes in the weather, use of different testing centers, use of different laboratory technicians, and so on. To combat this, the subjects would be put into groups of size t (not necessarily matched) and, apart from the assignment to different treatments, all subjects within a group would be tested under the same experimental conditions.

If the number of treatments, t, to be compared is large (as is often the case in a factorial experiment where the treatments are combinations of several stimuli), there may not be enough subjects to form groups of t similar subjects nor may it be possible to hold conditions constant for t measurements. In this case, an incomplete block design can be used, where each group of $s(<t)$ subjects is assigned at random to a preselected subset of s treatments (see, e.g., Winer, 1971: Chapter 9; Dean and Voss, 1999: Chapters 11, 13).

Within-Subject Designs

In a within-subjects design, each subject is essentially matched with himself or herself and assigned a sequence of some or all of the treatments. The order or presentation is decided using randomization for each subject separately. The comparison of any two treatments is made for each subject ('within' each subject) and then averaged over all the subjects. This has the advantage that subject-to-subject variability does not play a part in the comparison of the treatments.

In experiments where stimuli are presented to each subject in quick succession, 'carryover effects' can be a problem. For example, a subject asked to work in bright light followed by normal light may perceive the normal light to be darker than if it had been preceded by dim light. These carryover effects can be mitigated by separating the trials by a period of time, called a 'washout period,' in which the subject is asked to do something completely different in some control state. If a long enough washout period cannot be arranged, then the experiment usually is counterbalanced (see Section Latin Squares). Carryover effects are also known as 'residual effects' and the effect of the treatment administered in the current time period is called the 'direct treatment effect.'

Crossover Designs

In the simplest within-subjects design, any randomization of the order of treatments for any subject is accepted. However, if time period effects or carryover effects are thought to be important and are to be included in the model, then it is desirable to exercise control over which treatment sequences are used. In most cases, the carryover effect from a given treatment will be assumed to be the same no matter which treatment follows it. If the treatments interact, then this assumption may not be valid and larger designs and more complicated analyses are needed.

When the number of treatments is small, say two or three, and the subject can be measured over several time periods, then each subject can be assigned some or all of the treatments more than once. For three time periods and two treatments (one assigned to one period and one assigned to two periods), there are 6 possible treatment sequences; with four time periods and two treatments (each assigned to two periods), there are 14 possible treatment sequences; with four time periods and four treatments (each assigned to one period), there are 12 possible sequences, and so on. If there are sufficient subjects, all the possible sequences can be used an equal number of times. If the number of subjects is small, however, it may not even be possible to use each sequence once. Information must then be used about which set of sequences provides the best design. Among the possibilities are 'variance balanced designs' (see Section Balanced Crossover Designs) and 'Latin squares' (see Section Latin Squares).

In general, if it is possible to avoid them, two-period designs are not recommended. Not only can the carryover effects not be estimated independently of the treatment by period interaction but also three-period designs are considerably more efficient (Jones and Kenward, 1989: Section 4.16).

Balanced Crossover Designs

Crossover designs that allow differences between all pairs of treatments to be estimated with the same precision are

called 'variance balanced.' Variance balanced designs include crossover designs that use all possible treatment sequences, and counterbalanced Latin square designs (see Section Latin Squares). Variance balanced designs, efficient for comparing all pairs of treatments, are tabulated by Ratkowski et al. (1993: Chapter 5) and also by Jones and Kenward (1989: pp. 212–214, 223–224). The latter authors also list designs efficient for comparing test treatments with a control.

The treatment given in the last period of a crossover design can be repeated in an extra period. Such designs, called 'extra-period designs,' allow the carryover from the last treatment to be measured, thus increasing the precision of the treatment comparisons.

Balanced designs typically require a large number of subjects when the number of treatments is large and so cannot always be used. An alternative is to use an efficient 'partially balanced' design. These designs allow treatment differences to be estimated with two or three different precisions that are fairly close in value. When the treatments are factorial in nature, the effects of the individual factors (main effects) and the interactions between the factors are usually of primary interest. Variance balance is then desirable for the comparisons of the levels of each factor separately (see Jones and Kenward, 1989: pp. 222–228; Ratkowski et al., 1993: Chapter 6, for tabulated designs).

Latin Squares

A Latin square design is ideal for any experiment in which it is possible to measure each subject under every treatment and, in addition, it is necessary to control for changing conditions over the course of the experiment. A Latin square is a design in which each treatment is assigned to each time period and to each subject the same number of times (see Dean and Voss, 1999: Chapter 12). If there are t treatments, t time periods, and mt subjects, then m Latin squares (each with t treatment sequences) would be used.

Carryover effects are controlled by using Latin squares that are 'counterbalanced' (Cotton, 1993). This means that, looking at the sequences of treatments assigned to all the subjects taken together, every treatment is preceded by every other treatment for the same number of subjects. Counterbalanced Latin squares exist for any even number of treatments and for some odd numbers of treatments (e.g., $t = 9, 15, 21, 27$; see Jones and Kenward, 1989: Section 5.2.2, for references). For other odd numbers, a pair of Latin squares can be used, which between them give a set of $2t$ counterbalanced sequences.

If a carryover effect is expected to persist for more than one time period, then the counterbalancing must be extended to treatments occurring more than one time period prior to the current treatment.

Other Designs

Nested or Hierarchical Designs

It is not unusual for extraneous variables to be 'nested.' For example, if subjects are recruited and tested separately at different testing centers, the subjects are 'nested within testing center.' If subjects are animals such as mice or piglets, then the subjects are naturally nested within litters, which are nested within parent, which may be nested within laboratory. The nesting information can be used in matched designs, since the nesting forms natural groupings of like subjects. For within-subjects designs, the nesting information can be used during the analysis for examining the different sources of extraneous variation. Designs in which different levels of nesting are assigned different treatment factors are called 'split-plot designs' (see Section Split-Plot Designs).

A second type of nesting is a nesting structure within the treatment factors being examined. Examples given by Myers (1979) include memorization of words within grammatical class, time taken to complete problems within difficulty levels, and so on. Models and analyses used in such experiments must reflect the nested treatment structure.

Split-Plot Designs

An experiment with more than one type of stimulus (factor) can be run as a split-plot design with a level of one or more factors being applied to a subject throughout the course of the experiment (as for a between-subjects design), and the levels of the other factor(s) being changed for each time period (as for a within-subjects design). Such designs are sometimes called 'mixed designs.' The stimuli applied as the within-subjects design will generally be measured more accurately than those applied as the between-subjects design, since subject-to-subject variability enters into the comparison of the latter.

Split-plot designs are useful when it is difficult to change the levels of one of the factors. For example, Dean and Voss (1999: Chapter 19) cite an example of an optokinetic experiment on the drift of focus of a subject's eyes from the center of a rotating drum measured under two different lighting conditions. The change of lighting conditions was a time-consuming process, whereas it was simple to change the speed of rotation of the drum. Consequently, each subject was assigned a single lighting condition throughout an entire viewing session, and during the viewing session the subject was assigned a sequence of different speeds.

Optimality and Efficiency of Designs

As pointed out by Cotton (1998), designs that are best (i.e., optimal) for one purpose are not necessarily best for another purpose and compromises may need to be made. The optimal design for investigating the effects in one model may be totally unsuitable for a different model. For example, in a crossover design with two treatments and two time periods, a set of counterbalanced Latin squares provides an optimal design for estimating direct treatment effects and carryover effects. This design does not, however, allow estimation of both a carryover effect and an interaction between treatments and time periods. Thus, if both of these effects are required in the model, then more than two time periods must be used in the experiment.

As a general rule, the most balanced designs are optimal when interest lies equally in all treatment comparisons. The following features are typical characteristics of balance: every treatment is assigned the same number of subjects, every treatment is observed in every time period the same number of

times, and every treatment is preceded by every other treatment (including itself, if possible) for the same number of subjects and in the same number of time periods. When balance is not achievable, computer programs for generating optimal designs are commercially available. For other settings, where comparison of all treatments is not the main goal of the experiment, more sophisticated algorithms are needed; see, for example, Atkinson and Donev (1992) for a discussion of design optimality from a Bayesian perspective.

Abstract

Randomized controlled experiments are designed so as to make fair comparisons about which of two or more interventions works better, and to produce the least equivocal evidence possible about the relative effects of the interventions. The studies of impact may also be called randomized trials or social experiments depending on the particular focus. This article covers these kinds of studies in diverse academic disciplines and service delivery areas, different countries, and various geopolitical jurisdictions.

Introduction

This article defines randomized controlled trials (RCTs) and explains their rationale. The emphasis is on field studies that are designed to produce less equivocal evidence than laboratory experiments about what works and what does not. This article is studded with examples from education, crime and delinquency, social welfare, health care, and other areas. The handling transcends geopolitical boundaries. Important aspects of such trials are considered, including their history and practical concerns in their implementation. The last section references access to further information.

Definition and Rationale

In the simplest RCT, individuals are randomly assigned to one of two or more interventions. The interventions may be different intensities of social service, different mixes of therapies, and so on. The interventions may include a 'control' condition in which no services, or services that are ordinarily available, are provided. For example, to understand whether a new employment and training program works well, one could identify a pool of eligible participants and then randomly allocate some of those eligible individuals to the new program. The remaining eligible individuals are assigned to the alternative intervention. This alternative may be a normally available training service, i.e., a 'control condition,' or a program with a different service.

This random assignment of individuals to a new employment and training program and to an alternative program permits one to make a fair comparison of the outcomes, like wage rates, achieved by the people who were assigned to each group. The value that is added by a new program can be estimated well because the people who were assigned to the conventional services and to the new program do not differ systematically. In statistical vernacular, the comparison is unbiased. Put less formally, the groups are equivalent. Furthermore, one can take into account the chance differences between the groups' outcomes using conventional statistical methods. Both the idea of a fair comparison and the idea of taking statistical chance results into account are matters of serious interest, often but not always, in judicial settings (Kaye and Freeman, 2011).

To estimate the relative effect of a particular intervention, one has to estimate the status of individuals had they not had the intervention. This status is a counterfactual. At times, but not often, a precise forecast can be made about how individuals would fare in the absence of the intervention. Also at times, one may be able to construct what appears to be a fair comparison group, a counterfactual that represents the state of people in the absence of the particular intervention. Under these circumstances, statistical methods that undergird 'quasi-experiments' or 'observational studies' might then be employed to generate evidence about the relative effectiveness of programs. These approaches try to make a fair comparison of the outcome of alternative interventions based on sophisticated statistical models of how people behave, and on conscientious attention to competing explanations about why a difference in the effects of interventions might appear. See Rosenbaum (2010) and Morgan and Winship (2007), for instance.

Often, the researcher *cannot* make good forecasts, or construct defensible ad hoc comparison groups, or account for competing explanations for a difference among interventions in a quasi-experiment or observational study. A randomized trial may then be warranted because it assures that the comparison is unbiased. Because people or entities are randomly allocated into two or more groups, their equivalence assures that competing explanations for people's behaviors are taken into account. Both groups are subject to the same influences, apart from the interventions.

At times entities, such as schools, organizations, or geopolitical jurisdictions, may be randomly assigned to different interventions, rather than individuals. Different phrases are typically used to identify such trials. These phrases include cluster randomized trials, group randomized experiments, and place-based trials, e.g., Hayes and Moulton (2009), Donner and Klar (2010), and Murray (1998). Cluster and place randomized trials have increased in their frequency in developed and developing countries.

A Brief History

Randomized trials in medicine antedate such trials in the social sector. For instance, Claude Bernard's (1957) *Introduction to the Study of Experimental Medicine*, first published in 1865 in France,

outlined a framework for controlled comparisons though he said nothing about the topic of random assignment. In the late 1890s researchers in Denmark appear to have first used randomized groups to understand whether certain diphtheria serum worked (Hrobjartsson et al., 1998). During the same period, psychophysical experiments in German laboratory studies employed random assignment (Stigler, 1986).

Modern RCTs have their origins in the 1940s and 1950s, in studies undertaken by Bradford Hill and others in the United Kingdom to generate high-quality evidence on the effectiveness of streptomycin in treating tuberculosis. Later, Jonas Salk, Paul Meier, and others in the United States successfully used randomized trials to discern the effects of vaccine on the incidence of poliomyelitis. For readers with an interest in the history of randomized experiments in health and other sectors, see Marks (1997) and Maynard and Chalmers (1997).

In the social sciences, precedents include the graduated work incentive trials of the 1970s, tests of employment and training programs in the 1980s, and trials on welfare programs in the 1990s. Fienberg et al. (1985) discuss these and other large-scale economic and policy experiments, and how substantive theory is important in the experiment's design. See the Web site for the Social Research Demonstration Corporation for information on related work in Canada (http://www.policyresearch.gc.ca) or the ERN Digest of Experiments (http://www.ssrn.com/update/ern/ern_random-social-experiments.html) for contemporary reports on economic experiments in many countries.

RCTs have also been employed in education research. The Perry Preschool/High Scope trial on preschool education in the 1960s, for instance, is a precedent which demonstrated that intensive early education services can produce lasting educational effects. The Tennessee STAR trial in the 1990s was another milestone: a large-scale randomized trial on the positive effects of reducing school class size (Mosteller, 1999; Finn and Achilles, 1990). Other uses of randomized trials in education have tested new approaches to tutoring in England and the United States (Fitz-Gibbon, 1990; Fuchs et al., 1997), radio-based mathematics education in Nicaragua (Jamison et al., 1980), cultural enrichment programs for children in the barrios in Colombia (McKay et al., 1978), and cooperative group learning in elementary grades in Australia (Gillies and Ashman, 1998).

Boruch (1997) and Oakley (2000) provide early histories and other illustrations of RCTs; the following covers activity since 2000.

More Recent Examples in Diverse Countries

Randomized trials have been mounted in a growing area of research on microfinance and microenterprise in developing countries so as to estimate sustained benefits of such programs (see Karlan and Appel, 2011). Additional examples of randomized evaluation of economic interventions in developing countries include entrepreneurship promotion efforts in Tunisia (Almeida et al., 2012) and evaluation of the effectiveness of advice via mobile phones on agricultural productivity in Gujarat, India (Cole and Fernando, 2012).

In education, randomized designs have been used to test the effectiveness of conditional cash transfers that pay for families to keep their children in school. For instance, trials have been mounted in Mexico under the PROGRESA program (Behrman et al., 2009). RCTs have been employed to address the effectiveness of early schooling and tutoring on academic outcomes (e.g., Tymms et al., 2011) and trials are increasingly utilized in the evaluation of early schooling programs (e.g., Fantuzzo et al., 2011). Other investigations reflect an increased interest in randomized trials in Liberia, India, and Pakistan to assess different ways of enhancing school accountability (Bruns et al., 2011).

In the criminal justice sector, randomized trials in the United States have been deployed to estimate the effects of police handling of misdemeanor domestic assault, new approaches to courts' handling of certain cases, intensive police patrol strategies, and other interventions (Weisburd and Eck, 2004; Braga, 2001). RCTs on the 'Scared Straight' delinquency prevention program in the United States have identified unintended negative consequences of well-intended programs with 'Scared Straight' participants exhibiting higher rates of delinquency than the control group (see Petrosino et al., 2000). Experimental work in crime prevention, reviewed by Farrington et al. (2010), is occurring in Germany, Switzerland, the United States, and Canada with such trials providing valuable evidence on the efficacy, or lack thereof, for prevention programs across these different political contexts. Killias (2006) reviewed the implications of US work on randomized trials for criminological research in Europe.

RCTs are being employed around the world to test the effectiveness of behavioral health and social welfare interventions. In Switzerland, for example, randomized trials have been carried out to understand the effects of heroin therapy versus conventional treatment for individuals with drug addiction (Killias et al., 2000). Many randomized field trials have been used in Burkina Faso and South Africa, among others, to test behavioral and social approaches to health care, in health testing, and to reduce the risk of various diseases (Auvert et al., 2005; Bisoffi et al., 2009). Additionally, trials are increasing in frequency in the social welfare arena. Solomon et al. (2009) give an account of randomized trials in studies that have been mounted to test programs on psychosocial intervention and on social welfare reform.

Newer areas in which such trials have been mounted include political science. In some of these, the aim has been to understand the effects of campaign financing efforts and voter registration in the United States (Green and Gerber, 2003). More generally, the *Cambridge Handbook of Experimental Political Science*, edited by Druckman et al. (2011), provides an account of cluster randomized trials on plebiscites versus jurisdictional meetings in Indonesia, antiviolence initiatives in Nigeria, corruption detection and prevention in India, reconstruction programs in Liberia, election campaign strategies in Benin, and women's representation innovations in parts of India and Brazil, among others. Kinder's (2011) chapter in that handbook provides a social scientific history, giving attention to the seminal contributions of Donald Campbell.

Implementation of Randomized Controlled Trials

When a simple randomized trial involving two interventions is well designed and deployed, the statistical analyses are usually straightforward; textbooks for the design and statistical analysis

of results of such trials are readily available for single level and clustered trial (multilevel) scenarios (Maxwell and Delaney, 2004; Raudenbush and Bryk, 2002). The operational issues in deploying a field trial, however, are less frequently covered in textbooks. Nonetheless, a number of good sources are available to researchers who aspire to design and conduct one well. These include a special issue of the *Annals of the Academy of Political and Social Sciences* (volume 599, issued in 2005) in which managerial, institutional, and ethical challenges are addressed in cases drawn internationally from health, criminology, education, and welfare, all in the context of cluster randomized trials. A special issue of the *Journal of Experimental Criminology*, edited by Heather Strang in 2012 (volume 8, number three), covers management of experiments in crime prevention and reduction, emphasizing the coalitions that are involved and the development of relationships that assure a well-run trial.

For community-based interventions in the psychosocial services area, Solomon et al. (2009) provide guidance on implementation of trials and the interventions they are designed to test. See Boruch (1997) for earlier work along these lines. Many of the cases discussed in these works are attentive to various considerations in trials including tactics for assuring that the randomization process is not corrupted, that the deployment of the intervention is properly done, that cooperation among essential stakeholders is assured, and that the incentives and disincentives for adherence to the experiment's design are identified.

Other types of reconnaissance before conducting trials are also recommended. Statistical methods exist to plan the number of participants needed for the trial, and meta-analysis and systematic review can inform intervention design. Those conducting trials can capitalize on contemporary statistical methods and software to design a trial that maximizes their capacity to detect statistically significant effects. See, for example, PowerUp! (Dong and Maynard, 2013) and Optimal Design (Raudenbush et al., 2011). While accumulating and synthesizing results of randomized trials are also important in building the knowledge base about the effectiveness of social innovations, advances in meta-analysis and in systematic reviews can help to do this (see Cooper et al. (2009) for the technical state of the art and the Campbell Collaboration for illustrative high-quality products at http://campbellcollaboration.org).

Ethics and Law

For many countries the ethical standards for research (including RCTs) on human subjects have been influenced heavily by the Nuremberg Code and the Helsinki Declaration on medical research. Elements of these have been adopted, at times, to assure that the rights of people are protected in sociological, criminological, educational research, and other social research. The codes are pertinent to RCTs as they are to other kinds of studies.

Such codes usually require, for instance, that individuals be informed that their engagement in a trial is voluntary, if indeed it is, and that they can decline to participate or, having agreed to participate, that they can withdraw. Codes regard it as essential to provide a statement of possible risks and benefits to the participant. In the developed countries, an institutional review board is usually required to examine the experiment's design in order to assure that ethics' standards are met.

Such professional codes have been embodied in government regulations. In the United States, for example, the US Code of Federal Regulations (45 CFR 46) requires that most research organizations in the United States abide by these kinds of standards. Canada, the United Kingdom, and the Nordic countries have analogous regulations. Ethical standards are often reified in law. That is, legislatures, diets, parliaments, and other law-making bodies can influence decisions about whether randomized trials are run. In the United States, for instance, welfare laws that were enacted during the 1990s permitted various states of the United States to depart from national rules. This permission to depart from national law was in the interest of testing unconventional approaches to enhancing the education and employment status of low-income families. Such 'waivers' are an important vehicle for deploying and testing innovations that allow for ordinary societal interest in social improvement.

Until recently, no code of ethics of any professional organization considered directly the topic of trials in which entire organizations or geopolitical jurisdictions or other entities were the targets of random allocation. The absence of such handling led to questions about whose consent ought to be elicited in a trial, whether informed consent could indeed be elicited, how one thinks about risks and benefits, and so on. A Canadian group has developed a series of papers and a consensus document to clarify issues and options (Weijer et al., 2012).

One of the paradoxes of codes of ethics for researchers is that codes of research ethics have not been applicable to professionals who experiment in an uncontrolled way by 'trying something out.' Despite the absence of unequivocal evidence on a treatment's efficacy, for example, a physician may use the treatment on a patient without any ethics board review and without the informed consent that is required in a randomized trial. Similarly, a teacher who tries out new ways of teaching may do so without oversight by any institutional review board.

The designer of a randomized field trial can use at least four simple strategies to tailor the trial's design so as to conform to good standards of ethics and law. In the first place, if a purportedly effective service is in short supply, relative to the demand for the service, random assignment of people to the service can often be justified. That is, many people regard a lottery as the fairest way to allocate a scarce resource.

Second, people recognize that the eligibility of individuals for a particular intervention is an important ingredient in their design of a trial. For example, some criminal offenders clearly need to be jailed. Other offenders clearly should not be put into jail. For still others, the effectiveness of jail would not be known. The randomized study would focus then only on those for whom the benefit of jail to the individual is uncertain. That is, one designs the trial so as to include only those for whom the intervention's effectiveness relative to prison is uncertain.

A third strategy to the ethical design of randomized field trials involves a wait-list approach. That is, equally eligible people are randomly allocated into a group that receives treatment early and others are randomized to receive treatment later. The experiment then compares the state of two groups after the first has completed treatment and before the second group has begun.

A fourth strategy recognizes that, in some cases, random assignment of individuals to treatments is unethical (or infeasible) but recognizes that the random assignment of entities to different interventions is ethical. The trial's designer, for instance, may find that local juvenile facilities are unwilling, on ethical grounds, to assign individuals randomly to different treatments in their facility. The trialists may also find, however, that the same facilities are willing to try out interventions whose effectiveness is unknown, so long as the entire facility is randomly assigned to the intervention. See examples elsewhere in this article on such cluster randomized trails.

Institutional Capacity for Randomized Controlled Trials

Doing a randomized field trial also requires the understanding of managerial issues in field research and how to handle the cultural, ethical, and political-institutional factors that must be taken into account. Over the past 20 years, organizations such as the American Institutes for Research, Manpower Demonstration Research Corporation, Abt Associates, and Mathematica Policy Research conduct large-scale experiments in the United States and at times in low- and middle-income countries. Reports on the issues involved in implementing such studies are given in newsletters issued by the organizations and on their Web sites. In Canada, the Social Research and Demonstration Corporation has done so.

Other organizational arrangements have been developed in universities to facilitate managing and conducting small- to medium-scale trials. In the United Kingdom, for instance, the University of York has created a specialized Institute for Effective Education to this end, and University of Durham has a cadre of people who conduct such trials in the UK and elsewhere in collaboration with researchers from other countries.

Access to Information about Randomized Controlled Trials

Until the early 1990s, there existed no central source of information on randomized trials undertaken by health care researchers. In 1993, the international Cochrane Collaboration (Maynard and Chalmers, 1997) was created to prepare, maintain, and disseminate systematic reviews of studies on the effects of health care programs. As part of its mission to produce systematic reviews, the collaboration evolved into an important major source of information on randomized trials. The Cochrane Library is accessible at www.cochrane.ac.uk.

Until the year 2000, no organization had been invented to provide ready access to randomized trials in education, crime and justice, social work and social welfare, and other social sectors. The international Campbell Collaboration was developed as a younger sibling to the Cochrane Collaboration. The Campbell Collaboration's mission, in part, is to identify trials, screen reports on experiments for their quality, and produce systematic reviews of them. See http://www.campbellcollaboration.org/.

Over the past decade, a number of specialized journals and organizations have been created to focus on design, execution, and reporting on such trials. The peer-reviewed journals that contain full reports on the design and results of trials and that are web accessible include the *Journal of Research on Educational Effectiveness* and the *Journal of Experimental Criminology*. The *Randomized Social Experiments eJournal* produces frequent newsletters in which abstracts of reports on new controlled trials, mainly in economics, are routinely provided, and hyperlinks to full reports are given where possible. See http://www.ssrn.com/update/ern/ern_random-social-experiments.html. *Clinical Trials* focuses mainly on the medical sector but does include coverage of social and behavioral aspects that influence the interventions being tested in the trials (http://ctj.sagepub.com/). Edited handbooks on social research nowadays typically include chapters on experiments, e.g., *Handbook of Quantitative Criminology*, *Handbook on Practical Program Evaluation*, and *Handbook on Applied Social Research*.

Standards are also necessary for reporting on randomized trials to determine their credibility of findings and the extent to which they were run properly. The CONSORT Statement in health is fundamental (http://www.consort-statement.org/consort-statement/overview0/). The guidelines have been adapted to social fields including education; see The What Works Clearinghouse, http://ies.ed.gov/ncee/wwc/. In the prevention research arena, guidelines have been expanded by Flay et al. (2005) on design and execution of studies of efficacy and effectiveness and worthiness of dissemination, and by Valentine et al. (2011) on replication standards.

This article is a revision of the previous edition article by V.L. Smith, volume 8, pp. 5100–5108, © 2001, Elsevier Ltd.

Abstract

This article provides an introduction to the method of laboratory experimentation in economics, an overview of a selection of experimental studies, and a discussion of the findings and frontiers of this area of research. Emphasis is placed on how lessons from the economics laboratory are related to and can complement ideas and theory in other scientific subfields.

Introduction

Experiments overseen by economists have multiplied exponentially over the past 30 years. Experiments were once the province of the 'hard sciences' and psychology, whereas they now enjoy a respected and stable place in the economist's methodological toolbox. This article summarizes the defining features and scientific contributions of the modern subfield of experimental economics, describes the relation of economic experimentation to other methodological approaches in economics and to related research streams in social and behavioral sciences, and discusses the potential of economic experiments for progressing frontiers in both scientific knowledge and policy.

The Potential of Experimentation in Economics

Why do scientists perform experiments? Ostensibly, they want to test theories in progress in a fashion that allows them some control over the setting in which that test occurs. A well-designed experiment is one whose results allow scientists to reject, overwrite, or refine their operating understanding of the key quantities and governing dynamics at work in generating observed phenomena. By its very nature hence, experimentation is inextricably bound to theory. In the social sciences, 'theory' means what Croson and Gächter (2010) describe as "a description of a social situation, which involves specifying the actors, the choices they face, their information, and how they evaluate each possible outcome" (p. 123). A good theory in social science is a stylized representation (model) of 'situations in general' that can be applied to many complex real-life situations to deliver reasonably accurate predictions of the behavior of humans in those situations. To test whether a working theory is consistent with observed behavior, testable implications can be derived from that theory and built into an experimental design. To isolate the impact of one particular aspect of an accepted theory, the experimental design aims to hold 'everything else' constant, allowing the scientist to record outcomes in response to variations in only the level or pitch of the focal aspect. To horse race the usefulness of two or more working theories, competing implications can be drawn from each and a design sought that enables a direct comparison of the relative strength of support for the implications of each model. These are the sorts of agendas pursued through the various experiment-based methods in economics, which include the design and implementation of field experiments, the ex-post exploitation of 'natural experiments' created by policy quirks or acts of nature, and the design and implementation of laboratory experiments, which are the focus of this article.

While the discipline of economics has arguably delivered the most powerful standard model of human behavior, which is used today in some form or another to guide governmental policies and corporate decisions around the world (on the macroeconomic level, the mainstream model is well-represented by the writings of some of its founders (e.g., Paul Samuelson), and is reflected in what is taught to students of the discipline; on the microeconomic level, the main thrust of mainstream economic argument is simple: individuals respond in predictable ways to incentives (including, but not limited to, those embodied in market signals), no modern social science offers an internally consistent theory that fully explains the extreme complexity of human behavior. Hence, experimentalists across the social sciences – including in economics – perenially find that their initial theories in progress are inadequate to embrace all their observations. This leads to a natural process of refining the theory, running more tests, doing more refining, running more tests, and so on, in the continual pursuit of a deeper and more perfect understanding of behavior. These processes pursued simultaneously by many researchers can ultimately lead to a fundamental restructuring of basic theory, which holds the potential for true scientific advance. Until this restructuring occurs, scientific discourse commonly revolves around particular previously unexpected yet replicated phenomena that then provide an engine for generating hypotheses that only indirectly connect with those initial theories that motivated the original experiments. Modern experimental economics, with its incredible variety of applications and its range of obliquely connected results, can be argued to be in such a stage today (see Smith, 2010; Roth, 2014 for extended and thoughtful discussions of this phenomenon). Future breakthroughs in core economic theory, the backbone of the economics discipline, may yet be driven in part by the contributions of experimental economists.

Disciplinary Context and Constituents of Economics Experiments

The term 'experimental economics' generally refers to the subset of explorations by economists that is informed by

laboratory experiments. Yet economists today are also very active in the design and implementation of field experiments and in the capitalization, sometimes in collaboration with government administrators or policy makers, upon events in the real world that simulate a controlled experiment – often referred to as a 'natural experiment.' Field experiments, often aimed at testing the effects of particular institutions or policy interventions on individual behavior or aggregate social outcomes, are used frequently by researchers in institutional economics (e.g., Olken, 2010), public economics (e.g., Lacetera et al., 2013), and development economics (see Duflo, 2006 for a review). Natural experiments, in which subjects do not even know that they are participating, have been sought and exploited by those working in fields such as labor economics (e.g., Card and Krueger, 1994; Siminski, 2013) and health economics (e.g., Chou et al., 2010). Some of the economics discipline's most well-known work, including much of what is presented in the blockbuster popular science book *Freakonomics* (Levitt and Dubner, 2005), is the product of research that has exploited field or natural experiments.

By contrast, laboratory experiments designed and run by economists typically involve creating stylized representations of reality that are then presented to real people (experimental participants) in a controlled laboratory setting. Experimenters typically want to determine whether, and under what conditions, models of individual decision making, strategic interaction among agents, and/or market dynamics 'work' in the sense that their implications are consistent with the observed behavior of experimental participants. To this end, experimenters design a stylized world that specifies with greater or lesser precision the institutions that constrain and support decision making and choices (e.g., rules about what types of decisions are feasible, and information technology, such as whether participants know what other participants own or are doing, or whether it is costly to acquire this information), the available resources, and the 'payoffs' that accrue to each participant in each possible state of the world that might arise in the experiment. These payoffs are typically denominated in experimental or real-world currency, made known to participants, and are paid out to participants in real-world currency at the conclusion of the experiment according to the realized state(s) of the world (naturally, experimental subjects may be motivated by factors other than their monetary payoffs in the experiment, and often this is implicitly offered as a reason why subjects' behavior is observed to deviate from what might be expected based on a rational calculus of monetary profit maximization). Some experiments include uncertainty about more than merely what other subjects will choose – for example, the process by which an outcome is generated may be affected by random chance, or participants may face a choice of investing in a risky lottery.

The Theoretical Backdrop of Experiments in Economics

The design of economic experiments is frequently informed by game theory, decision theory, theories of industrial organization, and/or nascent ideas in the relatively young subfield of behavioral economics. These overlapping subfields, together with fundamental tenets derived from standard economic theory (e.g., that people respond to incentives), either singly or in combination provide the lens through which most experimental results in economics are interpreted by practitioners. The relevance of these subfields to the design of economic experiments is briefly reviewed below.

Game theory is the study of models of multiagent social situations in which individuals face choices whose effects depend more or less directly upon the choices of particular others. Game theory expands the scope of mainstream economic theory, because the latter's presumption of large, well-functioning markets rejects a personal social feedback element: in the standard model, no one individual's actions should be able to affect the market signals (chiefly, prices) that others use as inputs to their decisions, meaning that no one individual should rationally be swayed toward or away from any particular course of action merely because of the action of another individual. In game theory, by contrast, focal players are finite in number (usually numbering in the single digits) and can typically affect, though not unilaterally determine, the outcomes for everyone. The stylized models built of players' interactions in such models, which include settings for institutions, information availability and precision, resource endowments, and individual objectives, are often mathematically complex and challenging to solve. Game theory has been seminal in motivating some of the original games played in the laboratory, including most famously the Prisoner's Dilemma game and other instances of 'social dilemmas' (described more fully below), and has also motivated experiments designed to observe behavior in auctions and bargaining settings. However, the implications of many modern game theoretic models are unhelpful for the design of economic experiments. This happens most glaringly when it is found that in most possible specifications of a model, the possible equilibrium outcomes (i.e., the set of constellations of choices from which no individual has an incentive to deviate) are infinite. Additionally, economists' theories of individual decision making that game theory models try to animate do not yet feature a widely accepted, simple, and satisfying (as opposed to ad hoc) incorporation of motivations other than pure monetary self-interest, despite the fact that the existence of such motivations is often deduced from experimental results. These are the two primary reasons why modern game theory models are not more widely used as scaffolds for the design of economic experiments today.

Industrial organization theory, a branch of applied game theory, has delivered predictions about behavior in particular concrete interactive settings, from simple dyadic games like principal agent problems up to and including entire markets. By focusing on the behavior of profit-maximizing firms and/or their representatives, partners, employees, or competitors in particular well-defined and constrained situations – an area where mainstream economic theory has proven its predictive validity time and again – industrial organization (I/O) theorists have largely been able to circumvent the morass of accurately capturing those elements of individual choice that may be driven by phenomena other than pure monetary self-interest. I/O theory has generated clear and robust predictions about behavior under contrasting market structures (e.g., monopoly vs oligopoly), information structures (e.g., asymmetric or perfect),

and transaction cost levels, which can be relatively easily incorporated into experimental designs and manipulated by the experimenter. The relative clarity, tractability, and specificity of the implications of these models have meant that they underpinned the design of some of the first economic experiments (see Plott, 1982 for a review) and are still frequently used today.

Decision theorists examine many dimensions of how individuals decide how to allocate their resources (e.g., money or effort) or how to set their beliefs (i.e., their mental models of the world). It is distinct from game theory inasmuch as the social element of choice is frequently included only obliquely: the main focus is often not on calculating or interpreting the final result of the many interdependent choices of an entire interacting band of decision makers, but rather on specifying the decision process of a single agent or a set of agents, operating independently. Models of individual decision making contributed by economists include most famously those that specify the internal mental models and/or preferences of individual agents (such as subjective expected utility theory) and also those that specify particular mental idiosyncrasies (such as a reliance on mental heuristics) that may taint choice. These aspects of the underpinnings of choice may guide experimental design and the interpretation of results, but are arguably impossible to manipulate in a laboratory setting, since experimental subjects come in the laboratory door with them already in place.

'Behavioral economics' is the catch-all term for studies of the behavior of individual decision makers that appears, on the face of it, to be at odds with the behavior that would be predicted by mainstream economic models in which individuals act rationally with the aim of maximizing their own material gains. The reasons behavioral economists have proposed for why observed behavior deviates from these mainstream predictions include elements such as emotion, bounded rationality, internal relations with the unseen, systematically biased information processing, and the satisfaction of psychological needs, none of which are included in mainstream economic models. The developing theories of institutional economists also frequently contain some of these elements and have also given rise to laboratory experiments (e.g., Dal Bó et al., 2010). However, as with decision theory, the direct experimental manipulation of these dimensions of human motivation and behavior is arguably impossible or at best highly challenging, meaning that experiments can deliver more suggestive evidence than conclusive proof that these dimensions exist and are important.

Games That Are Played

Within the modern experimental economics community, particular features of design and protocol have endogenously emerged as strong norms to which one is expected to adhere in order for one's research to be considered acceptable (similar guidelines for 'best practice' arguably also exist for field experiments conducted by economists (see List, 2011)). These norms include the following.

No Deception

How much information do experimental subjects have about what is happening in the experiment? At one end of the continuum, subjects might be lied to outright about what the experiment is about, the level or determinants of phenomena that theory predicts should influence their behavior, and so on. At the other end, subjects might be told everything, from the minutest detail of the mathematical process being used to deliver an observation on a particular phenomenon, up to and including the precise hypothesis that the experimenter aims to test. The norm in the field at present is somewhere between these two extremes: researchers are expected to describe to participants in reasonable detail what will actually be happening in the experiment, and not to lie to them outright; but it is neither considered necessary to tell participants every detail of every process nor is it always considered either necessary or desirable to reveal the purpose of the experiment, since in many cases one might argue that doing so would irrecoverably change subjects' behavior away from what they would otherwise be inclined to do. This norm is particularly striking in its opposition to norms in experimental psychology, where outright lying to subjects followed by ex-post debriefing, while not universally accepted, are far more common (see Korn, 1997 for a review).

Careful of 'Endowment Effects' and 'Framing Effects'

Experimenters have found repeatedly that subjects appear to attach more value to objects that they perceive as theirs already, than to objects that they do not (yet) own. This often-replicated phenomenon, underpinned by Kahneman and Tversky (1979) and more concisely and generically described as reflecting 'reference-dependent preferences' or 'loss aversion,' has given rise to a concern that no behavioral result found in the laboratory be interpreted as something other than reference dependence when it could be explained by that alone. Merely using language or signals that frame a resource as already in a subject's possession has been found to alter subjects' behavior. Many other types of 'framing effects' – changes in behavior as a result of using particular language or signaling, rather than as a result of changing the parameters of the material problem being faced by subjects – have been found by experimental economists and are hence another focal area of concern in interpreting results.

Careful of 'Learning Effects'

Many economic experiments involve facing a particular decision-making scenario repeatedly. The standard concern is to ensure that observed behavior is interpreted only after partialling out any changes that may have resulted from subjects' learning, over the course of repeating the game many times, how the game really works or how to perform better. This is a particular problem when the task is complex and/or when there is doubt about whether the subjects understood the instructions, meaning that extended delivery of clear instructions with plenty of time for subjects to ask questions and/or be tested on their understanding of the instructions are hallmarks of modern economic experiments.

Incentivize Focal Choices

As mentioned above, a central tenet of economics is that people respond to incentives, or, in other words, that the absence of incentives will often produce different behavior than what

would result when incentives are in place. For this reason, and because they wish to be able to use their results in thinking about real-life settings where incentives are in play, experimental economists typically associate monetary incentives for subjects with whatever decisions of subjects they aim to interpret. Again in contrast to many experiments in our sister social sciences, subjects in economics experiments do not merely consider what they might do in a hypothetical situation with no real monetary stake in the outcome; they act out stylized representations of real situations, with real money on the line.

Experimenters in economics also pay particular attention to the randomization and anonymity requirements of whatever experiment is being run. The concerns here involve ensuring that behavior generated in the laboratory is not tainted by preexisting relationships among subjects, tacit expectations between subjects and the experimenter ('experimenter effects'), or nonrepresentativeness of the laboratory sample. On this last point, regardless of how close the experimenter gets to mimicking reality in the laboratory, any experimental result is inevitably vulnerable to the critique of low 'external validity' – in other words, poor confidence that insights based on the results can be used to interpret situations outside the laboratory. This concern in greater in situations where subject descriptors like age, experience, or culture, whose distributions are often truncated in subject pools, are expected to play an important role in determining behavior or behavior-relevant beliefs. Partly for this reason, and also because any number of other particular details of an experiment may be unique, replication – as in any experimental science – is considered the gold standard for generating support for the robustness of results.

Variations on a suite of workhorse game types are frequently presented to participants in economic experiments. These games are often programmed in specialized software, of which two popular examples are zTree (Zurich Toolbox for Ready-made Economic Experiments) and Mouselab. A brief sketch of the most popular workhorse games and some of the results they typically generate are given below.

Individual Decision-Making Games

These games feature no interaction between subjects, and focus on exploration of various aspects of how people make decisions. A common example is investment games, which offer subjects a risky investment opportunity and study how they behave under varying settings of risk, return, market signals, uncertainty, and so on (for example, as discussed in Harrison and Rutström, 2009).

Trust Games

Ultimatum bargaining games (popularized by Güth et al., 1982) provide a resource endowment to a subject who is offered the opportunity to give a portion of it, of his choosing, to a partner. The partner who is offered a share of the endowment is then allowed to either accept the offer (in which case it is 'paid out,' meaning that the division of the endowment proposed in the offer is implemented for both participants), or reject the offer, in which case both participants receive nothing. Economic theory suggests that the recipient should accept any positive offer made, since something is better than nothing, and therefore that the offerer should offer a tiny amount and expect this offer to be accepted by the recipient. The standard finding in the laboratory is that while significant heterogeneity across subjects exists (see Oosterbeek et al., 2004), on average a substantial share but less than half the initial endowment is offered and is accepted by the recipient. Dictator games, an outgrowth of ultimatum bargaining games, begin like the ultimatum game but the partner has no option but to accept the dictator's choice. Economic theory as animated in noncooperative game theory suggests that persons with the opportunity to be dictators should simply keep the entire endowment for themselves. The standard finding in the laboratory is that, by contrast, most people in the role of dictator share some of their resources with their partner. See Engel (2011) for a review.

Coordination and Cooperation Games

These include variants of the Prisoner's Dilemma (depicted in Figure 1), and public goods games where participants are given an initial endowment and the choice to invest part of it in a social good from which everyone in the game will benefit. Where theory predicts that the socially best outcome is not an equilibrium (and hence will not be reached by laboratory participants), such as in the case of a one-shot Prisoner's Dilemma, the term 'social dilemma' is applied. The standard result in Prisoner's Dilemma games, whether one-shot or repeated, is that people do not always play 'confess.' This has sparked much discussion of why that is, and in what situations denial is, more or less likely (e.g., Andreoni and Miller, 1993).

Market Trading Games

These games aim to mimic an actual market, such as the market for pollution permits or the market in which workers are matched to employers, often in order to validate theories about how such markets should be designed so as to maximize social welfare. See Roth (2002) for a discussion.

Auction Games

These games implement auctions for objects of value, often in order to validate theories about how to design auctions so as to maximize social welfare. See Kagel and Levin (2008) for a review of work in this area.

Years of prison to serve: (Player 1, Player 2)		Player 2: Confess	Player 2: Deny
Player 1	Confess	(5, 5)	(0, 6)
	Deny	(6, 0)	(2, 2)

Figure 1 The canonical Prisoner's Dilemma.

Economists have also used many other types of customized games in their attempts to mimic particular real-life situations of interest. See Davis and Holt (1993) for a more extended discussion of the variety of game types that have been used, their theoretical underpinnings, and their analytical targets.

Crossing Disciplinary Boundaries in Economics Experiments

As noted above, mainstream economic models have been claimed to be inadequate to explain some of the behavior that economists and other social scientists have observed in the laboratory (see Erev and Greiner, 2014 for a fuller discussion). Any latent phenomena that do not appear in such models are potentially present in any experiment, as a result of the prior conditioning of subjects, and despite their best efforts, experimentalists cannot fully control these phenomena, if indeed they exist. Also, subject heterogeneity, the effects of which are controllable to an extent via randomization but that, nonetheless, has been found in many studies, is not the main focus of mainstream economic theory featuring agents that are either identical or differ only along particular proscribed dimensions.

For these reasons, some economists have reached outside-of-their-home discipline to look for ideas and explanatory frameworks with which to guide and interpret their work. In particular, economic theory is weak in capturing the full set of factors (including nonmaterial factors) that may influence a decision maker's behavior, and it is weak in capturing group-related phenomena, with industrial organization theory being a partial exception inasmuch as a firm is a group. Unsurprisingly then, the disciplines whose contributions are most heavily drawn upon by experimental economists to help interpret their results and even in some cases to help design their studies are psychology, sociology, and political science.

Emotion and Cognition

Modern experimental economists are keenly aware that their subjects may have mental models, habits, or limitations that influence their beliefs and behavior in the laboratory. A few aspects of these psychological and neurological phenomena that have drawn particular attention in the experimental community are mentioned briefly below.

Fairness, Altruism, or Inequality Aversion

People's observed behavior in trust games, reviewed above, and in other games in the laboratory has been suggested to be the result of inbuilt commitment to some notion of generosity or sense of fairness. Ideas and jargon formerly the province of psychology, such as 'empathy' and 'altruism,' have thus made their way into the frameworks and parlance of economic experimentalists (e.g., Andreoni and Rao, 2011).

Cognitive Load and Heuristics

It has been vociferously argued (e.g., Tversky and Kahneman, 1974; Gigerenzer et al., 1999; among many others) that due to limitations and tendencies of the human brain, information presented in laboratory experiments – and indeed in the real world – is processed in a biased or incomplete manner, a contention of psychology for generations. This comes with clear implications for framing information (discussed above) and the wisdom of running experiments in which the instructions are complex.

Functional magnetic resonance imaging studies have on occasion been drawn on to motivate or interpret experimental results run by economists (e.g., Delgado et al., 2008). The brain remains today a highly mysterious organ, and it would appear that significant scientific advances are required before neurological evidence can lead to fundamental advances in those strands of behavioral theory that claim particular mental or emotional traits to be important in explaining behavior.

Group Dynamics

As evidenced by the recent proliferation of work in economic subfields that touch upon humans' interactions with and within their social groups (e.g., institutional economics, cultural economics, the economics of identity), economists increasingly recognize the role of group context and dynamics for individual behavior. It is particularly difficult to apply standard economic theory to this area of investigation, because of its omission of group-level phenomena from anything but the rather cold and often anonymous realm of buyers and sellers. How might people's behavior respond to incentives arising from social norms within companies, families, or countries? How do these incentives arise in the first place, how can we measure them, and what keeps them binding? These are questions for which coherent answers require either an expansion of core economic theory (a recent example of an attempt to offer such an expansion is Frijters (2013)) or a borrowing from sister disciplines that have asked such questions for decades, like sociology and political science.

Studying the nature of the interplay between individuals and their real-world groups is difficult in the laboratory, since subjects come into the laboratory with their group-related identification, norms, and habits already set. However, some economic experiments have tried to create new groups in the laboratory that mimic the rules and context of real-world groups. A particularly popular approach is to set up a leadership scenario with the potential for redistribution or exploitation by the controlling elite of common-pool resources, complete with voting and/or resource control rules, intended to mimic modern democratic groups such as the nation-state (e.g., Cabrales et al., 2012). This type of setting has been used to try to isolate the contributions of institutions such as rotating leadership, anonymous choice, socially mediated punishment, and power inequality to individuals' behavior (including exploitative and prosocial behavior) and aggregate welfare outcomes.

The Usefulness of Economic Experiments in Progressing Policy and Science

Laboratory experimentation by economists has delivered important evidence both in favor of, and against, the predictive validity of standard economic theory. In the former arena lie

many results regarding the optimal design of auctions and markets, and these results have been used to design actual markets in the real world, with powerful real welfare gains. Prime examples of this are Al Roth's kidney exchange program and the design of spectrum auctions.

While it has generated a proliferation of results, where the experimental method is weaker at present is in providing unambiguous guidance about phenomena that could help to refine our scientific theories of human decision making and social behavior. Debates presently rage about whether laboratory results that have been interpreted by some as evidence of altruism, bounded rationality, group norms, or other phenomena that deviate from the mainstream economic view of the economic agent in fact require an expansion of core theory, or are instead the result of particular experimental settings and do not extend to real-world decision making. Arguably, even if such phenomena do influence human behavior, identifying and measuring their causes (such as loyalty to one's nation state) using experimental methods will surely prove challenging. Nonetheless, experimental economics today is a thriving subfield and should be expected to keep delivering useful, intriguing, and controversial findings for years to come that will gradually push the discipline toward progress.

Experimental Laboratories: Psychological

Daniel Greenberg, College of Charleston, Charleston, SC, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Experimental laboratories in psychology are a bit different from the typical hard-science lab; in fact, to the casual visitor, they look a lot like ordinary office space. Nevertheless, these labs generally need certain features to be viable, including dedicated research space, reliable access to participants, and equipment for participant testing. The precise needs vary from investigator to investigator, and this article does not attempt to cover them all; rather, it seeks to provide a sense of the key issues that arise when investigators, department chairs, and administrators set out to build a new psychology lab.

Laboratory-Based Research on Human Participants in Psychology

Research in psychology can range from surgical experiments on nonhuman animals to observational research on social groups. This article will focus on noninvasive research on human beings – research that includes controlled experiments, pseudoexperiments, natural experiments, and observational research. (The lab needs of animal researchers and neuroimaging researchers are substantially different and will be covered in a separate article.) For instance, a psychology department's roster might include the following:

- A cognitive psychologist studying the heuristics people use to make decisions.
- A neuropsychologist investigating the effects of brain damage on learning and memory.
- A physiological psychologist measuring the galvanic skin response (GSR) elicited by emotionally evocative stimuli.
- A developmental psychologist conducting observational research on family dynamics.
- A social psychologist carrying out survey research examining health behaviors in college students.

This list is by no means comprehensive; it merely serves to provide a sense of the kinds of research that are done in psychology, and thus the kinds of facilities that might be needed.

The Fundamentals

Lab Location

Whatever the lab's focus might be, it must have a space that is consistently quiet. A loud sound at the wrong time can ruin a painstaking afternoon of data collection in an instant, and a lab situated in a noisy environment is useless. A modicum of soundproofing can be helpful, but it is particularly important to pay careful attention to what is located above, below, and behind the proposed laboratory space. Furthermore, potential participants must find it easy to access the space. For undergraduates, this is rarely a problem; however, other participants may require additional resources, such as convenient parking, an elevator, a waiting room, or a nearby restroom. These points may seem obvious, but they are critical: Participants will not come unless they find the experience agreeable, and a lab without participants cannot function.

Lab Design

Most psychology labs have a relatively straightforward design. The author's lab at the College of Charleston provides an example of the sort of space that is suitable for a midsize regional school that focuses on undergraduate education (a lab at a major research university would likely require more space). The lab is separated from the remainder of the building by a long hallway, and there is a small waiting room that is shared with another investigator. The lab itself consists of a main room with four small testing rooms attached, two on each side; the main room is roughly 18 m^2 (200 sq ft) whereas the testing rooms range between 5 and 9 m^2 (60–100 sq ft). The rooms have typical institutional furniture, including chairs reserved for participant use, and a number of desktop or laptop computers.

This lab is probably the simplest possible model; it focuses on paper- and computer-based cognitive testing of older and younger adults, so no elaborate equipment is required. Naturally, investigators with different research programs will have different needs. In developmental and observational research, for instance, a wall between the two testing rooms might contain a one-way mirror, which would allow investigators and research assistants to observe participants' interactions. In addition, cameras can be set up to record participants' activities, and microphones can be run through a drop ceiling. Researchers studying spatial navigation or driving might need a room dedicated to a virtual–reality setup. Other researchers rely on a battery of standardized psychological tests such as the Wechsler Adult Intelligence Scale (WAIS) or the Woodcock–Johnson battery. Still others might need specialized equipment to measure physiological variables such as blood pressure, pulse, or GSR (a change in skin conductivity indicative of physiological arousal). The requirements are limited only by the imagination of the investigator and (more relevantly) the resources of the institution.

Recruiting Participants

Of course, a well-built and well-stocked lab is useless without participants, so participant recruitment is one of the key concerns of any researcher in experimental psychology. Researchers need to be able to test enough participants to ensure adequate statistical power provide sufficient external

 http://dx.doi.org/10.1016/B978-0-08-097086-8.41028-7

validity, and allow for testing of both control and experimental groups. Consequently, researchers have developed a number of strategies for participant recruitment.

Undergraduate Participant Pools

Many studies in experimental psychology are conducted on undergraduates enrolled in introductory psychology classes (also known as the 'subject pool' or 'participant pool'). Investigators rely on participant pools because they are readily available and inexpensive to test because these participants are typically compensated by receiving credit toward their grade in their introductory psychology class; moreover, the participants are accustomed to taking tests and answering questions, and will typically perform with adequate diligence and effort. According to standard ethical principles, they must be given an alternative to participation in research, such as writing short research papers or summaries of journal articles.

At larger institutions, managing the participant pool becomes a logistical challenge, which is why most institutions rely on web-based systems. Experimenters who want to use undergraduate participants are given accounts on the system, allowing them to post experiment times, descriptions, durations, and locations. They can set a cutoff time by which participants must sign up to participate (for instance, an available time slot can be set to disappear if it is not filled 24 h in advance), making it easy for experimenters to plan out their day. The system can also be set up to send reminder e-mails, or even reminder text messages, at a specified time. Investigators can also set up prescreening surveys or indeed administer entire questionnaires online. The system also makes it easy to grant or deny credit, track how many students have participated, and so forth. Students in introductory classes are given accounts as well, and thus they can easily enroll in experiments that fit their schedule, confirm or cancel appointments, contact experimenters, and track how much credit they have earned. At the end of the semester, system administrators and instructors can run reports on the entire subject pool, allowing them to award the correct amount of credit. While no system is perfect (and none can entirely prevent a certain amount of squabbling over no-shows, cancellations, appropriate amounts of credit, etc.), these web-based systems are generally a worthwhile investment.

Concerns About Undergraduate Participant Pools

In most cases, the undergraduate participant pool is supposed to be educational – that is, the students are supposed to learn something about psychology from the experience. Although students and researchers alike are sometimes skeptical of this notion, existing studies of this issue generally paint a more optimistic picture. Landrum and Chastain (1995) used a short questionnaire to assess the views of a small percentage of participants, and discovered that most of them found the experience to be educational. Bowman and Waite (2003) found that students who participated in research were more satisfied than those who pursued the alternatives; they also found that students had a better understanding of research procedures and a more positive attitude toward psychology. Similarly, Elliott et al. (2010) found that students who participated in an experiment learned just as much as students who simply listened to a lecture or read an article about it, although the students generally found participation more enjoyable. Thus, on a pedagogical level, these experiences do seem to serve their stated purpose, at least when proper debriefing techniques are used.

On an experimental level, however, the reliance on undergraduates raises concerns about validity, in part because of continued skepticism about how representative these participants really are. As Henrich et al. (2010) have observed, undergraduates are generally 'WEIRD' – Western, Educated, Industrialized, Rich, and Democratic – and thus they are not a representative sample of humanity. In fact, as the university admissions office will be happy to point out, these psychology students are often not a representative sample of their age group either. They are not a representative sample of the students at their own university, where the majority of students may be enrolled in other subjects. They might not even be a representative sample of students in introductory psychology classes: a reasonable number of students choose the research alternative for a variety of reasons (see Elicker et al., 2010), and by definition nonparticipants are difficult to study. One investigation, however, has found that students who do participate are better students than those who do not (Padilla-Walker et al., 2005), suggesting that participants might differ from nonparticipants on tasks that draw on academic aptitude.

To make matters worse, the characteristics of participants are known to vary across the semester. Participants who show up earlier in the semester tend to be more conscientious and are more likely to be female (e.g., Witt et al., 2011). They may be more academically oriented, more compliant, and more introverted, and there is some evidence that they tend to have higher GPAs (see Aviv et al., 2002, for a review). Results for cognitive tasks have been mixed (see Zelenski et al., 2003, for a review). Nevertheless, the message is clear: A study can yield different results at different times in the semester.

Beyond the Participant Pool

These are longstanding concerns (Sieber and Saks, 1989; Sears, 1986, 2008), and they have led many researchers to seek out participants outside of the usual participant pool. In any event, undergraduates are simply not appropriate participants for certain lines of research, such as research on aging or early child development. The primary challenge in this approach involves recruitment. Naturally, participants will not magically show up at the lab door; they need to be recruited through advertisements (whether on paper or the Internet), flyers, and the like. In this way, researchers can build up a database of reliable participants. The word 'reliable' is important here, because investigators must avoid 'frequent fliers' – people who make at least part of their living by participating in research, and who are perfectly willing to be less than honest about whether they meet study criteria. A well-established and reliable database allows investigators to select participants who meet certain demographic criteria. It is important to note, however, that even a database like this is not static; it needs to be replenished on a regular basis as participants move out of the area, lose interest in participation, or pass away. The participants who do remain in the database will change with time and might one day fail to meet study criteria. Thus, recruitment is always ongoing – and so are the costs associated with it.

Participant Payments

These costs arise in part because participants outside the undergraduate pool typically need to be paid. For nonintrusive psychological research, the compensation is nominal – in 2014 US dollars, a participant might earn $10–15 an hour for participation in a simple behavioral study along with free parking. Nevertheless, participation rates drop substantially if compensation is not provided. Experience has shown that administrators and investigators should look into the method of paying participants *early* in the process of setting up the lab, because university financial offices are often unfamiliar with this practice and have been known to raise numerous objections. Here are some questions to ask: Can participants be paid in cash? Can they be given gift cards, gift certificates, or other items? Will they have to be paid by check, electronic transfer, or other similar mechanism? How long will it take to issue payment? Will participants have to disclose their address, social security number, tax ID number, or other personal information? Are there limits to how much participants can be paid in a single year? Who is responsible for tracking all of these? What sort of paperwork is required, what sort of records must be kept, and for how long? As a general rule, the more cumbersome and intrusive the paperwork, the less willing people will be to participate.

Hardware, Software, and Other Equipment

In the early days of psychology, researchers tested participants using all manner of clever mechanical equipment. These days, most testing can be done using fairly standard office computers equipped with specialized software. The brand names and the capabilities of the software packages change on a regular basis, but they all have one key feature in common: They provide experimenters with precise control (that is, on the order of tens of milliseconds) over the presentation of stimuli and the collection of responses. Ordinary office software cannot do this.

Most of these software packages have extensive capabilities that allow researchers to program almost any conceivable experiment. They can present sound clips, movies, images, or text. They can record responses using a keyboard, mouse, button box, joystick, and so on. They can even create 'branching' experiments in which the order of experimental trials depends on the person's responses – for instance, the experiment can be programmed to slow down automatically if the participants are making a large number of errors. Once the experiment has been run, the data can easily be exported to a variety of standard spreadsheet or database software, then analyzed with any of the standard statistical programs used in psychology (Matlab, Minitab, SPSS, SAS, R, etc.).

Online Testing

Other researchers test participants online. There are several ways to do this, including online surveys, and they do allow experimenters to collect massive amounts of data in a relatively short amount of time. Nevertheless, all of them involve several difficulties. For one, there is no straightforward way to know whether people are who they say they are, which only exacerbates the 'frequent flyer' problem. Second, online testing allows for less control over the participants themselves: one cannot readily know whether participants are completing the experiment while preparing dinner or using unauthorized resources to 'cheat.' Third, precise experimental control of timing parameters is more difficult online, particularly the millisecond timing that is important for many studies of cognition and perception. These limitations do not preclude online testing; they just mean that researchers must give some thought to the kinds of tasks that are appropriately administered online.

One possible avenue of administration involves Mechanical Turk, a service run by the web site amazon.com. Here, experimenters can post tasks for participants to complete – or, to use Mechanical Turk's terms, requesters can post human intelligence tasks (HITs) for workers. Experimenters can restrict their experiment to participants who meet specific criteria. Furthermore, participants are rated based on their performance (most relevantly, whether they completed the task promptly and adequately), which means that requesters can exclude participants who have proven unreliable in the past. Participants are paid through amazon.com, and the rates of payment are quite low – far lower than they are for in-person studies.

But are the results comparable? Several studies have examined this question. Crump et al. (2013), for instance, used Mechanical Turk to collect data on a series of standard cognitive tasks, such as the Stroop task, the flanker task, priming tasks, and so on. They found that the results were generally in accord with those obtained in the lab, but they also identified some important limitations. In particular, they recommend using some sort of measure to check whether participants understand the instructions, since participants have no easy way of asking questions during the task. They also recommend monitoring and reporting dropout rates, which tend to be higher in online experiments, and using caution when implementing experiments that require precise timing or detailed visual displays.

Conclusion

The traditional introductory psychology participant pool remains a common source of participants, but researchers are increasingly turning to online testing approaches to increase their sample size and recruit a broader and more representative group of participants. These changes might seem to foreshadow the end of in-person testing. Nevertheless, any number of experiments, such as those that involve millisecond timing, complex sensory stimuli, or certain forms of social interaction, simply cannot be run online with present technology. Even when running more straightforward experiments, there is simply no substitute for testing at least a few participants in person. Thus, the brick-and-mortar psychology lab will remain a fundamental part of the science for some time to come.

Experimental Laboratories: Social and Economic

Richard Gonzalez, University of Michigan, Ann Arbor, MI, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The experimental laboratory has become a key component in social and economic research. The article discusses how to prioritize the equipment and personnel needed to create a fully operational laboratory to answer research questions.

What is an experimental laboratory in social and economic sciences? A laboratory (lab) is defined as a place that contains equipment necessary for one's scientific work. Under this definition, the key phrase is 'equipment necessary.' In practice, the contents of a lab are dictated by the kind of research one does and the tools required to implement that research. The social psychologist studying communication patterns within a married couple requires a different lab than a social scientist studying the psychophysiological correlates of aggressive behavior or an experimental economist testing an implication of game theory. Sometimes a social science lab is merely a small room with a computer. As long as that space, and the equipment it houses, allows the research to be conducted, then the room can be called a lab. Much as Pygmalion carved his ideal mate out of ivory, a researcher creates a research environment from the equipment, setting, and people necessary to conduct research. Research labs will vary depending on the needs of the researcher.

The Computer

One piece of equipment that has become indispensable in just about all social and economic labs is the computer. At a minimum, the computer facilitates the editing of manuscripts. Writing experts claim that the ability to edit and rewrite one's prose is critical for clear, crisp writing. A sophisticated user of a word-processing program can format a manuscript in the manner required by a journal editor and easily construct a reference list from an electronic database. An Internet connection allows collaborators to exchange working drafts of articles either through electronic mail or shared disk space, and authors can submit manuscripts for publication electronically, as well as distribute reports to other interested parties. In this sense, the computer has replaced the typewriter as the machine used to write and the copier as the machine used to disseminate the written product of one's research. Dissemination of results is an important feature of all research projects – others need to benefit from the new knowledge that has been created.

There are, of course, more advanced uses of the computer in social and economic research. For instance, the computer can be useful in the selection of the research sample, data collection, and data analysis. Unlike the traditional paper-and-pencil questionnaire, administering a survey by computer permits automatic tailoring of follow-up questions depending on the answers the respondent provides to previous questions. Software can help to create and administer complicated sampling designs, and can facilitate elaborate laboratory procedures such as the presentation of research stimuli at a rapid rate, presenting questions in random order, or measuring the timing of a participant's response.

Some researchers have started placing their studies on the World Wide Web to complement their lab and field data collection (e.g., see http://www.socialpsychology.org/expts.htm and Amazon's Mechanical Turk Web site https://www.mturk.com/mturk/welcome). Researchers may allow unlimited access to their study or grant limited access to a select subsample. Care must be taken to create a representative sample. Sampling issues aside, conducting studies over the World Wide Web makes it convenient to collect data at multiple sites from any number of computer platforms. This permits data collection anywhere in the world at relatively little expense.

Computers are also used to analyze data. A simple spreadsheet program can be used for descriptive statistics and simple inferential tests, whereas specialized software is needed for more computationally intensive data analytic techniques such as bootstrapping and Bayesian algorithms. Even the analysis of some forms of qualitative data (such as narratives) can be facilitated through the use of software programs designed to code original text. For example, a word in the text could be coded as a noun, as a positive or negative word, or any number of other categories relevant to the particular research question.

The computer also aids lab management. For instance, scheduling and calendaring software can help organize interdependent parts of a research project on a time line. Such time lines are useful not only for facilitating the scheduling of lab facilities and lab meetings, but also for planning and writing grant proposals.

How many computers should a lab contain? What kind of computer should a lab have? These questions are difficult to answer in the abstract because so much depends on the research question. For example, one project may involve 200 handheld tablet computers because the study requires 200 married couples to answer questions each evening at home for a month. On the other hand, a researcher who studies social interaction through computer simulation may only need one computer with fast processors and extra memory. In sum, the needs of the research drive the equipment required in the lab.

What Is Your Research Question?

It is useful to consider three factors when designing a lab for social or economic research: the experimental context the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.41029-9

researcher needs to conduct the research, the methods the researcher will use, and the measurements the researcher will make. Each of these three issues is subsumed by the following more general question: what is the research question? If your research question addresses how Mayans conceptualize kinship terms, then you would need a special setting, special materials, and special measures – the lab will likely need to be portable. This research question requires a different lab setup than, say, a research question about trust in the context of an economic game that can be conducted in a controlled setting of lab located in a university building.

What Experimental Context Does the Research Require?

What context does the research require? For example, if one wants to study social behaviors in a bar, then it might be useful to design a lab setting that resembles a bar (complete with mood music, barstools, and liquor cabinets). If one wants to study jury deliberation, then it is useful to design a lab setting that resembles an actual jury room. These labs can be constructed to reproduce, or mimic, a real-world setting, and hence increase the external validity of the research, especially if these details influence behavior to be more realistic.

However, it is also possible to study social and economic behavior in an artificial setting, an analog setting that evokes similar processes as the real-world setting but is easier to create and easier to control. One example is the classic Milgram (1975) study on obedience. Milgram claimed that his obedience findings could help us understand how citizens in a totalitarian government may be pressured to follow superiors, *but* his research setting was low in external validity with respect to totalitarian governments. Milgram's research setting was successful at evoking the processes that make it difficult to refuse requests or refuse to follow orders. Milgram's lab setting involved an elaborate stage production that the experiment was about the effects of punishment on learning. *However*, the actual purpose of the study was to examine the social interaction between the participant (who believed he or she was playing the role of the 'teacher' in the study on learning) and the experimenter. Milgram's work is useful in demonstrating that much can be learned from artificial experimental settings. One must be careful, however, not to extrapolate too much from such artificial circumstances because of the loss of external validity.

Sometimes the researcher must assume the role of a stage manager in a theatrical company. The researcher attempts to create the setting that produces the reaction in the participant required by the research question. This may frequently include the use of stage props, as in the Milgram study that used a machine to administer (bogus) electric shock to the 'learner.' The role of a stage manager should not be underestimated. Social psychology experiments frequently are criticized for being low in external validity, but a study that engages the participant in the task is high in another important feature mundane realism (see Aronson et al., 1992, for a discussion of validity and mundane realism). As much as possible, studies should try to engage the participant because a bored, disengaged participant is likely to provide low-quality data.

Some research questions can be studied in a relatively simple setting. For instance, research investigating people's facial reactions to disturbing photographs would need a means for displaying the pictures (a slide projector, a computer, a photo album), so an appropriately lit room would be a sufficient setting. The participants could be videotaped while viewing the photographs and trained coders could rate the facial expressions. With the proper cameras and software it is also possible to use computer algorithms to automatically code the facial expressions in real time.

Tools for the Research Method

One of the defining features of an experiment is that it includes a manipulation, also known as an independent variable. The goal is to create at least two conditions that differ only on the particular feature that is manipulated. Random assignment of research participants to condition facilitates this goal.

Laboratory equipment may be needed to conduct the manipulation. For instance, work on eyewitness identification of a criminal suspect may require that the composition of the lineup be varied to include foils that are either high in physical similarity to the suspect or low in physical similarity. Thus, if the researcher uses a photolineup, then the lab should include a broad range of photographs so that many different lineups could be constructed.

A computer can be useful in carrying out experimental manipulations. For instance, if the manipulation requires varying the duration a stimulus is presented, then the computer can be used to control such durations. Experimental stimuli may involve presentation of video or animation and a computer can facilitate the creation, editing, and presentation of such material.

Sometimes the manipulation requires the use of drugs. For instance, research on arousal may require the participant in one condition to receive a dose of epinephrine whereas a participant in another condition to receive a dose of a neutral sugar pill. Some researchers in decision-making use oxytocin to manipulate trust while playing an economic game. Such research requires equipment necessary to store and administer the drugs and in some cases appropriate medical professionals on site. Careful attention should be given to proper tracking of the use of the substances such as storing them in a safe that requires two people with different keys to access. Participants should be cleared for safety prior to leaving the study. For example, a study examining behavior in an experimental bar that involves consuming alcohol should ensure that participants are not intoxicated when leaving the lab.

Measurement Devices

An important feature of empirical work is that something is measured. Even qualitative research has measurement, such as the recording and interpretation of a narrative. The lab must include the tools necessary to make and store such measurements.

Standard measurement devices include an audio recorder, a video recorder, a computer with interactive software, and pencils for participants to write responses. Some research may also require measurements of the electrophysiology of the brain or autonomic nervous system, which requires specialized equipment to store and analyze samples (e.g., measurement of cortisol level in saliva).

Some experiments may require the use of standardized scales such as personality tests, intelligence tests, or scales to measure depression. Because some of these scales are copyrighted, researchers may need to contact the developers of the scale for permission to use. Again, which scales are needed in the lab depend on the research question. For instance, if the research question examines the relation between intelligence and aggressive behavior, then scales to assess intelligence would be needed on hand.

Managing a Lab

Much like large offices, some experimental labs may require a lab manager to handle the day-to-day functioning of the lab. The manager's tasks may include scheduling the use of lab resources, monitoring research budgets, and staying abreast of manuscript and grant proposal deadlines. Sometimes a lab requires more specialized personnel, such as a technician when electrophysiological recording equipment is used or a programmer if specialized software is needed. Lab personnel may also handle maintenance of lab equipment and storage of data.

Summary

New researchers frequently ask, 'What kind of equipment should I include in my lab?' As argued in this article, one should reply with the following questions: What is the research question? What experimental setting is needed for the research? What equipment is needed to conduct the research? What equipment is needed to collect and analyze the measurements? How will the administration of the lab be handled?

Abstract

Randomized controlled trials (RCTs) have been profitably used to identify causal effects in population research. However, the design and implementation of social experiments is not straightforward and it is not clear that it is either feasible or desirable to attempt to answer some questions in population using only the so-called 'gold standard' double-blind RCT. It seems likely that the integration of the creative use of theory with the advantages of both RCTs and nonexperimental study designs has the greatest hope of advancing scientific knowledge about population behaviors and processes.

Introduction

A goal of population research is to isolate causal effects of, for example, policies, programs, circumstances, and behavioral choices. For example, what is the causal effect of improved access to family planning services on the health and economic status of women? What is the impact of marriage on health and well-being? What is the impact of migration on those who move and those who are left behind? Answering these types of questions with observational studies is challenging because the counterfactual is typically not observed: what would have happened if the migrant had not moved is not known. It is difficult to separate the impact of the stimulus (the decision to migrate) from other, unobserved factors that distinguish those who experience the stimulus (those who choose to migrate) from those who do not (those who do not choose to migrate). The promise of social experiments is that they provide a method for putting aside these unobserved differences and, thereby, identify causal effects.

In the ideal randomized controlled trial (RCT), study subjects are randomly assigned to receive a stimulus (the treatment group) or a placebo (the control group). After the stimulus, the difference between the average outcome of the treatment group and the average outcome of the control group provides a measure of the causal effect of the stimulus on the outcome. Because the study subjects are randomly assigned to receive the stimulus, concerns about what drives selection into each group (or unobserved differences between the groups) are, by design, put aside.

Implementation of the ideal RCT is far from straightforward in the best of circumstances. Implementing social experiments to address important questions in the population sciences is very challenging. To examine the impact of migration, for example, one cannot simply move a randomly selected group of people to a new location and force them to remain there while forcing those in the control group to stay put. It may be possible, however, to subsidize the costs of migrating, broadly defined, or, in the case of international migration, adopt a policy of randomly assigning visas to a subset of those who apply. Aspects of each of these designs raise important issues regarding the question that is addressed and the interpretation of the estimates. The central point is that social experiments have the potential to be very valuable in population research but, as is the case with observational studies, they have strengths and weaknesses.

Indeed, beyond identifying causal effects, it is important to understand the mechanisms that underlie behavioral choices. To this end, it seems the greatest promise of RCTs and social experiments lies in their fuller integration with theory and observational designs to advance understanding of population processes, a position advocated by Heckman (2010).

Historical Perspective

RCTs have a long history that, according to Stigler (1992), dates back at least to Peirce's work in psychology (Peirce and Jastrow, 1885). The statistical foundations were formalized in the 1920s by Neyman (1923) and Fisher (1935) and the methods were used in the agriculture sciences to evaluate the impact of inputs and practices on output. RCTs were later adopted in medicine to evaluate the impact of treatments on patients and, it is often argued, that double-blind RCTs are the 'gold standard' for evidence in that field. Whereas randomization of agricultural plots is relatively easy, randomization with human subjects is more complicated, particularly when the stakes – life or death, for example – are high. Without question, randomized controlled social experiments are even more complicated to design and implement.

In the 1960s and 1970s, several large-scale, influential social experiments were fielded to examine, for example, the impact of providing an income guarantee through a negative income tax (Orcutt and Orcutt, 1968), of varying the costs of health insurance (in the RAND Health Insurance Experiment, Newhouse et al., 1996), and of providing job training to youth and unskilled adults (Bloom et al., 1997). In the population field, studies in demographic surveillance sites in Navrongo, Ghana and Matlab, Bangladesh pioneered the use of social experiments to investigate the impact of improved access to family planning and maternal and child health programs on health and well-being (Phillips et al., 1988, 2006).

In recent years, the adoption of RCTs has exploded, particularly in development economics, led in large part by Banerjee and Duflo along with their colleagues, many of whom are associated with the Abdul Latif Jameel Poverty Action Lab at MIT (Duflo, 2007; Duflo et al., 2008; Banerjee and Duflo, 2009, 2010, 2011). Deaton (2009, 2010) has been a leading critic of the

rise of RCTs in the field. Over the last 20 years, Heckman (1992, 2010) has played a pioneering role in exploiting the advantages and addressing the disadvantages of social experiments.

The Ideal RCT

We begin with the ideal or 'gold standard' RCT in which study subjects are randomly assigned, at the individual level, to a treatment or a control group, with neither the study subjects nor investigators knowing who has been assigned to which group (that is, the study is double-blind). To lay the foundation, consider the linear model

$$\theta_i = \beta_0 + \beta_1 T_i + \varepsilon_i \quad [1]$$

in which $T_i = 1$ if individual i is treated and 0 if not. The goal is to estimate β_1 to measure the causal impact of a stimulus or treatment, T_i, on the outcome of interest, θ_i. Put another way, we are interested in estimating

$$\beta_1 = E\left[\left(\theta_i^T - \theta_i^C\right)\middle|T_i = 1\right] \quad [2]$$

where θ_i^T is the outcome when an individual is treated and θ_i^C is the outcome when the individual is not treated. For example, we may be interested in measuring the causal impact of a treatment that improved physical health on hourly earnings. In this example θ_i^T is hourly earnings of a person who received the treatment (took iron supplements); θ_i^C is what the same person would have earned per hour in the absence of receiving the treatment. Obviously, the counterfactual, the outcome if the individual who was treated had not been treated (denoted θ_i^C in eqn [2]), is not observed. However, the difference between the average earnings of those who received the health-improving intervention and those who did not can be observed and so we can estimate

$$\widehat{\beta}_1 = E\left[\theta_i^T\middle|T_i = 1\right] - E\left[\theta_i^C\middle|T_i = 0\right] \quad [3]$$

Rewriting eqn [3]

$$\widehat{\beta}_1 = E\left[\left(\theta_i^T - \theta_i^C\right)\middle|T_i = 1\right] + E\left[\theta_i^C\middle|T_i = 1\right] - E\left[\theta_i^C\middle|T_i = 0\right] \quad [4]$$

we have

$$\widehat{\beta}_1 = \beta_1 + E\left[\theta_i^C\middle|T_i = 1\right] - E\left[\theta_i^C\middle|T_i = 0\right] \quad [5]$$

where the second and third terms in eqn [5] capture the effect of 'selection,' that is the impact on $\widehat{\beta}_1$ of unobserved heterogeneity, ε_i, correlated with the treatment, T_i, in eqn [1]. Returning to our example, the second term is the average earnings that the treatment group would have earned if they had not been treated, the counterfactual that cannot be observed. The third term is the average earnings of those who were not treated. If the difference between the second and third terms is zero then $E[T_i\varepsilon_i] = 0$ and $\widehat{\beta}_1$ is a consistent estimate of the causal impact of T_i on θ_i:

$$\text{plim}_{n\to\infty}\widehat{\beta}_1 = \beta_1 \quad [6]$$

On the one hand, if study participants who received the treatment would have earned more in the absence of the treatment than participants in the control group, then $E[\theta_i^C|T_i = 1] - E[\theta_i^C|T_i = 0] > 0$ and the treatment group would be positively selected, relative to the controls. In that case, $E[T_i\varepsilon_i] > 0$ and $\widehat{\beta}_1$ would be an upward biased estimate of the causal impact of T_i on θ_i. This might arise, for example, if subjects have to apply to participate in the treatment and those who apply are those who would have earned more even in the absence of the treatment. On the other hand, if, relative to controls, the study participants would have earned less in the absence of the treatment, then $E[\theta_i^C|T_i = 1] - E[\theta_i^C|T_i = 0] < 0$ and the treatment group would be negatively selected, $E[T_i\varepsilon_i] < 0$ and $\widehat{\beta}_1$ will be downward biased. This might arise if those with a lower value of time (and lower potential hourly earnings) are also more likely to apply for and participate in the treatment.

Experimental studies are designed so that the selection term $E[\theta_i^C|T_i = 1] - E[\theta_i^C|T_i = 0]$ is zero so that $E[T_i\varepsilon_i] = 0$ and eqn [6] is true. In a double-blind RCT, this can be achieved by randomly assigning subjects to either the treatment or control group and then exposing only the treatment group to the stimulus and, after the treatment has had an impact, comparing the outcomes (or changes in outcomes) of the treated and control subjects. In an RCT that is designed and implemented well, the second and third terms in eqn [5] will be zero by construction. The average treatment effect (ATE) is an unbiased estimate of the causal effect of the treatment on the outcome.

Key Features of the 'Ideal' RCT

There are at least three features of the 'ideal' or 'gold standard' RCT model that are critical for estimated treatment effects to be consistent. First, study subjects assigned to the treatment should be 'exchangeable with' those assigned to the control group; i.e., in terms of any characteristic that is related to the outcome of interest, the treatments and controls are effectively interchangeable.

In some studies, randomization is conducted after stratifying on observable characteristics (such as age, gender, race, education, or location) and study subjects are randomized within each subgroup. Analyses conducted on each subgroup satisfy the conditions necessary to interpret the estimated effects as causal. The reverse is not true: if study subjects are randomly assigned to treatment and control without stratifying by group, it is inappropriate to assume that the selection term in eqn [5] is zero within groups. For example, say you are interested in examining the effect of a treatment on males and females separately but randomization was not conducted separately by gender. We cannot assume that the selection term in eqn [5] is zero for all the study subjects and also for males as well as for females, taken separately. That may be true, and if so, then we are lucky. However, since it is not built into the study design, one cannot assume that it is true.

This also highlights that RCTs lean heavily on the assumption of linearity in eqn [1] since the mean of the difference between treatment and control outcomes is the same as the difference between the mean treatment and mean control outcome. Estimation of heterogeneity of effects calls for additional assumptions that may not be correct and will typically need to be justified by drawing on a theory or at least a mechanism that lies outside the RCT study design (Deaton, 2010; Heckman and Smith, 1995).

Second, attrition, which is a key concern in every longitudinal study, has the potential to be particularly pernicious in an RCT. If posttreatment follow-up is selected on benefits (or costs) to those in the treatment group relative to the benefits (and costs) to those in the control group, the attrition will potentially contaminate estimates of the treatment effect. Since outcomes of subjects who are lost to follow-up are not measured, the effects of attrition are necessarily absorbed in unobserved heterogeneity, ε, in eqn [1] and it is not obvious that it is reasonable to assume $E[T_i\varepsilon_i] = 0$. To address this concern, some RCT studies establish that attrition is unrelated to treatment status and, in some cases, to observed baseline characteristics. While such results are comforting, they do not establish that attrition is ignorable. For example, if attrition is related to the impact of the treatment – say those who do not benefit much from the treatment exit the study – then it may be difficult to detect this sort of selection in the absence of a posttreatment measure of the outcome of interest. In the 'gold standard' RCT there is no place for attrition; achieving that in a population-based study is a tall order.

The third critical feature of the double-blind individual RCT is that outcomes of the control group must not be affected by the treatment to assure that the second and third terms in eqn [5] are equal. This rules out, for example, any response by the controls to the fact that they were not selected for the treatment. In a double-blind RCT, neither the study subjects nor the study investigators know who is assigned to receive the treatment or who is assigned to the control group. In that case, neither the treatments nor the controls have the information necessary to change their behavior because they know they are (or are not) in the treatment group.

The 'gold standard' RCT study is double-blinded because a similar concern applies to study investigators who may treat those in each group differently, albeit implicitly. This sort of behavior has been described in some drug trials, even in double-blinded studies, as investigators have been able to infer who is in the treatment group (by examining biomarkers, for example) and have adjusted their own behavior or treatment in order to help the subject (see, for example, Lauritsen, 1990). Studies have also documented instances of nonrandom assignment of subjects to the treatment or control group. For example, in studies that have been implemented by people who have a stake in the outcome, or want the best for the subjects, and allocate those subjects whom they believe will benefit most from the treatment to that group. The double-blind design is intended to assure these types of contamination do not occur.

Implementation of Double-Blind RCTs in Population Studies

In an ideal study design, the RCT involves a comparison of the impact of a treatment with an identical looking placebo (which may be an alternative treatment) to assure the study is double-blind. This approach has been used in population research. For example, an RCT implemented in a district in Central Java, Indonesia, tested the hypothesis that health has a causal effect on economic productivity by comparing changes in hourly earnings of iron-deficient individuals who had been randomly assigned to receive iron supplements with earnings of controls who received an identical-looking sugar pill (Thomas et al., 2014).

However, many studies in the population sciences seek to measure the impact of treatments such as improved access to family planning or other health-related services; participation in an education or training program; access to credit, financing, or an income transfer program. In such cases, it is not possible to design a double-blind RCT because there is no placebo that can be given to the controls that appears to be identical to the treatment.

This raises concerns with contamination of the estimated treatment effect because of behavioral responses by study participants to random assignment or to the treatment itself. In a study of a training program, for example, if some of the subjects assigned to the treatment group choose to not participate in the program or drop out of the program before it is completed then it will not be possible to measure the program effect on those subjects. On the other side of the coin, if some of the subjects who are assigned to the control group participate in another, related training program, then the estimated treatment effect will be biased. One of the motivations for randomly assigning some people to participate in a program is because the program is oversubscribed. In this situation, treatments are more likely to participate in the program, but control subjects are likely to be more motivated to seek out alternatives to the program treatment. Move to Opportunity (MTO) is a major randomized housing mobility experiment that was implemented in the 1990s in which 4600 low-income families with children living in public housing in disadvantaged urban neighborhoods were offered the chance to move to private market housing in better neighborhoods. Families were randomized to receive a housing voucher that subsidized private market rents (with half of them carrying some constraints on where they could relocate) while the controls received no vouchers. Only about 50% of those who received a voucher managed to relocate to a better neighborhood and a substantial fraction of the control subjects also relocated (Ludwig et al., 2012).

Intent to Treat and Treatment on the Treated Estimates

One approach to addressing these concerns is to estimate the intent to treat effect which measures the impact of the program on all the subjects who were assigned to the treatment relative to all the subjects who were assigned to control, irrespective of whether they actually participated in the program. This contrasts with the estimate of the effect of the treatment on the treated (TOT) which includes only those subjects who complete the treatment and compares them with the controls. Clearly, the TOT estimate cannot be assigned a causal interpretation. Studies have used random assignment status as an instrument for participation in the treatment in an instrumental variables framework to identify the causal impact of the treatment on those who chose to participate. This does not provide evidence on the likely impact of the treatment on those who did not choose to participate (Heckman, 1992).

Level of Randomization

Another approach to addressing the concern that there may be behavioral responses by subjects to being assigned to the treatment or control group is to eschew randomization at the individual level and, instead, randomize at a higher level such as the community, school, health center, or microcredit agency. In this case, if the study is able to exclude people who are not in the community (or school etc.) at the time of randomization from receiving the treatment, then it is possible to mitigate the impact of behavioral responses to the treatment and control assignments. In practice, this can be difficult and may raise ethical issues. In addition, such a design may have unintended impacts on behavior.

PROGRESA is a very large and ambitious conditional cash transfer (CCT) that was implemented in rural Mexico after a rigorous randomized control trial. Parker et al. (2008) provide a description and review results from the evaluation. The evaluation study selected 506 low-income communities and randomly assigned about two-thirds of those communities to receive the CCT program in 1998 with the other third of communities being told they would receive the treatment 3 years later (although the treatment was provided to households in these communities 18 months after the evaluation began). The CCT was means tested at the household level based on a baseline survey. Over and above a basic transfer that depended on household size and composition, additional payments were made conditional on children's school attendance and participation by household members in activities at the health center. In some households, the payments were very large relative to their pretransfer income.

Studies have established that households that were eligible to receive the transfers had higher levels of spending, improved health and schooling outcomes, and invested more in productive assets. However, there is also evidence that noncoresident family members living in the same community as a beneficiary household also benefited from the program, indicating sharing of resources among extended families. This suggests that impacts of the CCT on outcomes in beneficiary households may be underestimated. On the other hand, the program was designed so that individuals and households could not move to a treatment community and receive the treatment; eligibility for the treatment was determined at the baseline survey. Moreover, if a member of a treatment household moved away from the community, the individual did not take the CCT with him or her and the baseline household payment was reduced accordingly. Migration out of poor rural communities is widespread in Mexico and it is a mechanism used to improve the well-being of both the migrant and those left behind. By design, the PROGRESA evaluation provides a disincentive for young adults in beneficiary households to move away in search of a better life. The same disincentive does not apply to young adults in households in control communities. This further complicates interpretation of the estimated impact of PROGRESA. Since the evaluation study did not follow movers, it is difficult to assess the likely magnitude or even direction of this effect. Moreover, attrition is a serious problem in the evaluation study: loss to follow-up is substantial (with about 20% of the study participants being lost by the second follow-up) and it is potentially selective. Nonetheless, PROGRESA has been judged a great success, was implemented across all rural and later to urban Mexico, and renamed Oportunidades.

Estimation of Variability

In model [1],

$$\theta_i = \beta_0 + \beta_1 T_i + \varepsilon_i$$

the variance of errors may not be the same among subjects in the treatment and control groups. Consistent estimation of the standard error of the treatment effect, $\widehat{\beta}_1$, is straightforward with an estimator that takes heteroskedasticity into account, such as the Huber estimator or the jackknife (Huber, 1967; Efron, 1982).

In studies, like PROGRESA, in which randomization is at the community (or group) level, rather than at the individual level, estimation of variability is more complicated. Rewrite model [1]

$$\theta_{ig} = \beta_0 + \beta_1 T_g + \varepsilon_{ig} \qquad [7]$$

where treatment, T, is defined at the group, g, level. Unobserved heterogeneity, ε_{ig}, varies across individuals and may be correlated within groups. Failure to take into account within-group correlations (or clustering) of residuals yields estimates of variability that are biased, typically (but not always) downwards. Adoption of an estimator like the Huber or jackknife estimator that allows for both heteroskedasticity and the block structure of the residuals provides consistent estimates of the standard error of the treatment effect.

Huber-type estimators do not perform well when the number of groups is small (say less than 15), the bias in estimators that ignore the problem can be quite large. A wild clustered bootstrap procedure has been shown to perform well in these situations (Cameron et al., 2008). While the concern arises in both experimental and nonexperimental studies, it is particularly salient in RCTs that randomize at the group level with few groups.

In some studies, the model is extended to include covariates, X, which may be measured at the individual or group level:

$$\theta_{ig} = \beta_0 + \beta_1 T_g + \beta_2 X_{ig} + \varepsilon_{ig} \qquad [8]$$

The idea is that, if randomization has not been violated, the covariates should have no impact on the estimated treatment effect, $\widehat{\beta}_1$, because they are, by design, orthogonal to the treatment. The role of the covariates is to absorb unobserved heterogeneity and thus increase efficiency of the estimates. The strategy is, however, not without controversy (Freedman, 2008).

Generalizability of Evidence

Population scientists are often concerned with the generalizability of results in both observational and experimental studies. However, it is discussed most often in the context of experiments that are conducted on selected subsamples. For example, some experimental studies are based on convenience samples of respondents who sign up for a study or are recruited for a study without paying attention to whether the study

sample is representative of a well-defined population of interest. The external validity or generalizability of results from such studies to a broader population is difficult to assess since there are potentially unobserved characteristics in the broader population that are not present in the study sample. In that case, one of the key advantages of the RCT design, that $E[T_i\varepsilon_i] = 0$, may not be true in the broader population and so little can be inferred about the generalizability of the evidence.

Experimental studies that use the oversubscription approach to recruit subjects are potentially prone to this criticism if the goal of the study is to provide evidence on the impact of the program beyond those who have signed up for it. For example, it is not clear that the results of the evaluation of a training program based on an oversubscription recruitment strategy will generalize to all the unemployed. This concern will arise if, relative to all the people who are eligible for a training program, those who sign up to participate are more motivated to do well, possibly because they have recently experienced a dip in earnings or a recent, short unemployment spell (Heckman, 1992). As with nonexperimental studies, it is possible to make additional behavioral assumptions in order to estimate bounds on the treatment effect and its distribution, potentially exploiting both the experimental variation itself and also the design of the experiment such as the potential outcomes for those who receive the treatment(s) and those who do not (Heckman et al., 1997).

Drawing out generalizable findings is more complicated when there are behavioral responses by the subjects to the study itself or to the fact that the subjects have been assigned to either the treatment or control group. These are often called Hawthorne effects which arise when study subjects respond to the stimulus of being studied. Again, this is a general concern in social research, particularly studies that involve intensive interaction between the subjects and investigators. The issue can be more complicated in experimental studies if subjects react to the fact that they were assigned to either the treatment or control group and draw inferences from that assignment. One of the difficulties with designing experimental studies is that it can be difficult to predict behavioral responses to the study or its design. For example, in an ambitious large-scale study of the impact of incentives on police performance in India, subjects in one arm of the study who were not selected for the treatment felt discouraged. This had a deleterious impact on their work effort and so the treatment (or lack of it) affected the behaviors and outcomes of the controls, substantially complicating interpretation of the results (Banerjee et al., 2014).

In many cases, observational and experimental research studies are small in scale which raises questions about both generalizability and whether the study results are likely to hold at a larger scale. For logistical and cost reasons, experiments are often conducted in a small number of study sites and, in some cases, the sites are selected because an implementing partner or institution is operating in that area. Generalizability will be compromised if the study results are driven by characteristics that are unique to the site or implementing partner. For example, if the implementing partner in a study of the impact of microcredit is a particularly effective microcredit provider in an area where the program has been established, it is not clear that study results will generalize to settings in which providers are not as effective or programs have not already been established. Similar issues arise with studies that involve schools or health providers that are committed to improve outcomes but are not representative of the full set of institutions that will be called upon to implement changes if the treatment is scaled up. These issues are familiar to population scientists and studies in the population field are often designed with subjects and study sites (and possibly partners and implementers) selected so that they are representative of a well-defined underlying population.

Equilibrium and Longer-Term Effects

Scaling up an experiment raises a related but different issue: there may be equilibrium effects that are not captured by measuring only the treatment effect. Consider an experiment in which the treatment that improves the health of subjects results in their being more productive (by providing iron supplements in an area where iron deficiency is widespread) and, as a result, say the treated subjects have more rice to sell on the market. There may well be equilibrium effects if the increased supply of rice results in a reduced price (if the local market is closed) or increased income in the community (if more rice is sold outside the local market) which may, in turn lead to increased opportunities for work. To explore these effects, the iron supplementation study in Central Java, Indonesia (Thomas et al., 2014), was designed so that the fraction of the population recruited for the study in each of the 146 desa (villages) varied and the fraction of the study subjects who were at risk of benefiting from the supplements also varied. In addition, some desa were randomly assigned to not receive either the treatment or the control so that they serve as additional controls, uncontaminated by the study itself.

In an RCT that provided rainfall index insurance to cultivators in India, demand for hired labor and market wages was more sensitive to rainfall with the insurance. This resulted in reduced uncertainty among cultivators but increased uncertainty among agricultural wage laborers. This effect would not have been observed if the study had focused only on the impact of the RCT on cultivator choices (Mobarak and Rosenzweig, 2014). The point is not that equilibrium effects are inherently bad (or good) but, as is the case in observational studies, drawing on theory to identify potential equilibrium effects and designing experimental studies to explore the empirical importance of such effects is likely to have a substantial pay-off.

Few experiments are designed to provide evidence on longer-term effects. From a theoretical perspective, the impact of a short-run increase in income is likely to be different from the impact of a permanent increase in income or an increase in income that is expected to last for the long term. It is difficult to infer the impact of a permanent increase in income with the PROGRESA design. This is an important limitation, inherent in many RCT studies that are designed to provide a treatment for a limited period of time. This is particularly important when effects of the intervention are likely to cumulate over time – as subjects save enough to start a business, for example. A similar issue arises in the RAND Health Insurance Experiment that randomly assigned health insurance with different co-payments and deductibles to subjects. The program was provided for 3 years. If the benefits of health insurance cumulate, the experiment is unlikely to

uncover the full benefits of the insurance. In fact, subjects who received the most generous benefits were more likely to have a birth during the 3-year window, indicating shifts in the timing of fertility in response to the time-limited nature of the experiment (Newhouse et al., 1996).

A related, but different, feature of many RCTs is that they are designed as stand-alone studies that do not follow subjects for the long term. In those cases, it is not possible to measure the longer-term impact of the specific (short-term) intervention. This is not a feature of RCTs, per se, but rather reflects the way many have been implemented, the costs of the studies, and the costs of longer-term follow-ups. In some cases, it is unlikely to be feasible to design and implement an RCT that will provide answers to question many years hence. For example, measurement of the impact of prenatal exposures or early childhood experiences on health and mortality at older ages is unlikely to garner much support. However, tracking subjects over the life course, and measuring the evolution of impacts over this period has the potential to be very profitable. Indeed the MTO evaluation as well as evaluations of the impact of early child interventions in adulthood (Hoddinott et al., 2008; Heckman et al., 2013; Campbell et al., 2014) are superb examples of the value added to science of following treatments and controls in RCTs over the long haul.

A complementary approach is to build randomized variation into broad-purpose longitudinal population-based surveys that are designed to follow individuals over the longer term, independent of the RCT. The Matlab Health and Socioeconomic Survey (MHSS) (Rahman et al., 1999) has been a pioneer in this regard. MHSS is a large-scale population-based longitudinal study that has been conducted in conjunction with a long-term demographic surveillance study conducted by "the International Centre for Diarrhoeal Disease Research, Bangladesh" in Matlab district, Bangladesh, and has been used to evaluate, for example, maternal and child health and family planning interventions (Schultz and Joshi, 2013).

Integrating Theory and Estimation with Experimental Designs

Recent studies have better integrated RCTs with theory and other research designs. An increasing number of experiments in the social sciences are designed to reach beyond measurement of an ATE of a program or policy and test theories about behavior or identify mechanisms that plausibly explain behaviors and outcomes. Many of these designs have roots in behavioral economics.

In an early example, Ashraf et al. (2006) designed a commitment savings product that was offered to a randomly selected sample of current and former clients of a bank in the Philippines in order to provide insights into intertemporal preferences and savings behaviors. Several studies have used experimental variation in combination with models to examine how price variation affects consumer demand; these studies have described, for example, the role that prices play in signaling information and how short-run subsidies affect consumption over the longer run (Dupas, 2014).

Another line of research exploits randomly assigned variation in experimental designs to validate estimation of complex structural models that have a strong link to the underlying theory and, by necessity, make potentially strong assumptions. Todd and Wolpin (2006) use data from the PROGRESA evaluation study to estimate a dynamic behavioral model of parental decisions about fertility and child schooling. Estimates are based on data from subjects collected prior to receipt of program income and model estimates are validated by comparing predictions of program effects from this model with experimental results. The model performs very well. This is important because, without this external validation, it is very difficult to confidently assess the quality of model estimates and, therefore, the assumptions underlying the model. Furthermore, the structural model is designed to conduct simulations of alternative policy designs – in this case conditional transfer schedules – and the authors conclude that the same program impacts could be achieved with fewer resources, a result that is consistent with conclusions, which Schultz (2004) drew based on estimation of PROGRESA program impacts.

Results from experimental studies have been profitably used to evaluate assumptions in observational studies (Lalonde, 1986). Currie and Thomas (1995) and Garces et al. (2002) use longitudinal nonexperimental survey data to examine the impact of Head Start on children, adolescents, and young adults by comparing siblings, one of whom attended Head Start and one did not. It is not obvious that this identification strategy is valid and so they assess the strategy by first replicating the main results from the Perry Preschool Project. That project is an RCT that measured the impact of early child education on poor children, and served as a model for Head Start. The use of nonexperimental data and methods provided evidence of the impact of Head Start on a broader and more diverse population than the Perry Preschool study population as well as the impact on outcomes and at ages that were not assessed in the Perry project. The credibility of the nonexperimental results depends critically on the validation from replication of the RCT results.

Conclusions

In principle, the ideal or 'gold standard' RCT is an extremely powerful tool for identification of causal effects in the population sciences. However, implementation of an RCT that meets this ideal is far from straightforward in medicine and is even more complicated in the context of social experiments. In practice, the design and implementation of an RCT in the population sciences is fraught with problems. But the same is true, arguably a fortiori, of observational studies. The key advantage of an RCT is that the investigator has the potential to randomly assign who is exposed to a stimulus or treatment that is of central interest to the study. One of the disadvantages is that the bigger the impact of the treatment, the more likely that study participants will seek to undo the advantages of randomization.

Garber et al. (2014) argue that "In the absence of theoretical or methodological breakthroughs, the only possibility for further learning comes from experiments, particularly experiments with strong external validity." It is unclear this is true: the argument that one approach to empirical inquiry dominates all others under all circumstances is extreme. Whereas some questions in the

population and social sciences are unlikely to be credibly answered without an experimental design, others are not amenable to experimental manipulation and cannot possibly be addressed with an RCT. RCTs are but one arrow in the population scientist's quiver and a potentially very powerful one at that. Rather than toss out all the other arrows, it seems likely that scientific knowledge about population behavior and processes will be advanced through the integration of creative use of theory with the clever design of both experimental and nonexperimental studies. Recent studies suggest that, at least in this regard, future prospects for the population sciences are very bright.

Abstract

Standardized experimentation constitutes the core of psychology's scientific identity. Since the 1940s, the ideal experiment has been understood to be an experiment comparing randomly composed experimental and control groups. This article discusses the historical origination of this 'random group design.' Whereas psychology textbooks generally attribute its origination to natural science, historical research suggests that comparing randomly composed groups is firmly rooted in psychology's *own* experimental traditions. Moreover, these traditions have changed together with changing social relations. The article discusses the 'psychophysical' research practices of nineteenth-century scholars trying to discover the given laws of human perception, and elucidates how these practices were adopted and adapted by twentieth-century educational psychologists looking for technically useful data. It also discusses the random group design's further dissemination and its current status as mostly a guiding model rather than a viable strategy.

From the very beginning of their studies, psychology students in Western countries learn that the discipline specializes in quantitative research rather than 'armchair philosophy.' Methodological and statistical textbooks teach how to measure individual or group characteristics such as intelligence, neuroticism, or attitudes. Moreover, introductory and advanced textbooks spell out rules of experimentation for tracing the causes of the psychological characteristics that are measured or evaluating attempts at improving them. Standardized experimentation in particular constitutes the core of psychology's scientific identity.

The typical psychological experiment compares one or more treated experimental groups to an untreated control group. As natural groups may vary in many more respects than only the hypothesized cause or treatment to be tested, experimenters must compose their own groups equal in all respects but the factor concerned. The ideal way to create comparable groups is to assign subjects to groups on the basis of chance and thus cancel out unwanted between-group differences. From the 1940s in America and from the 1960s in Europe, generations of psychologists have been taught that the *exemplary* experiment is an experiment in which randomly composed experimental and control groups are compared. Statistical inference testing is employed for establishing the significance of any differences in the results.

The Origins of the Exemplary Design

Psychology textbooks typically discuss the experiment comparing randomly composed experimental and control groups (from now on 'the random group experiment') as being 'the' scientific experiment. They implicitly suggest or explicitly state that this form of experiment was borrowed directly from the natural sciences (more on the definition of an experiment in psychology textbooks can be found in Winston and Blais, 1996). Yet, as has been demonstrated by researchers of science, in natural sciences such as physics and chemistry there are various ways of experimenting, and these are mostly learned during apprenticeship and via exemplars rather than through isolated methodology books and courses (Kuhn 1962). Moreover, comparing random groups is not a key experimental practice in such sciences (Hacking, 1983; Galison, 1997).

Historical research suggests that comparing randomly composed groups is firmly rooted in psychology's *own* experimental traditions, traditions which have changed together with changing social relations. The discipline's present-day definition of what constitutes an ideal experiment was brought about bit-by-bit when methodological practices from nineteenth-century 'psychophysical' experimenters trying to discover the given laws of human perception were adopted and adapted by early twentieth-century educational psychologists looking for technically useful data. These educational psychologists then passed the random group design on to other branches of psychology and social sciences (Danziger, 1990; Winston and Blais, 1996; Dehue, 1997).

Experimentation in Nineteenth-Century Psychophysics

Psychological experimentation began as an endeavor of mid-nineteenth-century gentlemen-scholars to discover the given design of human nature. The word 'experiment' could refer to all kinds of research other than naturalistic observation. Experimentation involved manipulating human sensation and perception within artificial situations. An important founder of psychological experimentation was the German scholar Gustav Fechner, who during the years 1845 to 1849 lifted his arms with a weight in each hand over 67 000 times. After each lifting, Fechner meticulously recorded whether he had been able to distinguish the heavier weight from the lighter. In this way he established the 'just noticeable difference' or 'threshold of perception' as well as the mathematical relationship between the weights as measured and the weights as perceived.

In Fechner's time, the claim to measure anything as subjective as human sensation was novel and impressive. In the second half of the nineteenth century, innumerable 'threshold experiments' were conducted in biology, physiology, and

particularly the newly established psychological laboratories at European and American universities. Countless extra weights were lifted, and Fechner's methods of 'psychophysical' experimentation were employed for testing other senses as well. A popular variation was touching the skin with two pins at specific distances and trying to establish the minimum distance that can still be perceived (see **Figure 1**). The different sensitivities of foreheads, chins, shoulders, arms, fingers, hips, bellies, legs, knees, and ankles were discussed. Neophytes would complain about sensitive and scaly skins and apologetically argue that some 6000 pricks should be enough to draw a conclusion (Dehue, 1997).

Like Fechner, the first psychophysical researchers acted as their own experimental subjects. Soon, however, the idea arose that the stimuli should be applied in random order, and that random control trials were needed. Researchers in Germany and subsequently the USA argued that the perception of distances might be biased by expectations on the next distance to come. Such expectations might be induced by awareness of the actual distances in previous trials or inadvertent regularities in previous series of trials. Moreover, it was argued, the sheer knowledge that there are always two pins might arouse the idea of perceiving a distance even if the actual distance is below the threshold of perception. For these reasons, it was decided that it takes *two* to experiment. Assistants were employed to apply the stimuli in random order as well as randomly carry out control trials in which the skin was touched at one point only without knowledge of the 'observers' (later on the individuals providing the stimuli would be called the 'experimenters' and the observers became the 'subjects,' see Danziger, 1990 on the social meaning of such terminological changes). These were the first experiments employing randomization as a methodological means. In the 1880s, the American scholars Charles S. Peirce and Joseph Jastrow, moreover, introduced the first *artificial* randomizers. Distrusting the assistants' ability to establish truly random orders, they used playing cards or dice (for a more extensive discussion and references, see Dehue, 1997).

If the stimuli are indicated as 'S,' the responses as 'R,' and the randomly applied control trials (in which the actual double prick was withheld) as '*noS*,' then the design of these experiments was something like S-R-*noS*-R-S-R-S-R-*noS*-R-S-R-*noS*-R-S-R-S-R (etc.). In later educational experimentation, the randomly inserted control trials (*noS*) were no longer conducted with the same subjects as the experimental trials (S) but with randomly composed control *groups*. This change implied the constitution of the random group design. In order to explain why that happened, some extra information should first be given on the methods of early psychophysics as well as social changes taking place outside the laboratories.

The 'Transfer of Training' Phenomenon

Considerable concern about individual expectations and mistaken assessments became the hallmark of psychophysics. For the sake of replicability, utmost precision had to be exercised. The initiators of particular experiments extensively described the required laboratory setting, the instruments to be used, the handling of the instruments, as well as the required behaviors of assistants and observers both during the trials and in their spare time (Morawski, 1988; Benschop and Draaisma, 2000).

The researchers of just noticeable differences, however, were confronted with a rather obvious extra source of bias. After many trials, the *skill* of the experimental subjects improved, and this artificially lowered the threshold of perception. Switching to the other arm or leg did not solve the problem because the undesirable training seemed to transfer automatically to other parts of the body. The transfer phenomenon thwarted the experiments but also greatly intrigued the experimenters. Many of them became so fascinated by it that from a source of bias 'transfer of training' became a research topic of its own. At the end of the century, experiments were being conducted in American and European laboratories to establish the effects of training in all kinds of sensory, motor, and cognitive skills. Subjects were not only pinpricked. They were also asked to put needles through small holes with one hand and then checked for improvement with the other hand, or they were trained to tap their right big toe and tested for their ability with their left big toe (Bray, 1928).

One has a mental picture of distinguished-looking men in suits sitting on wooden laboratory chairs and fiddling with needles or concentrating on their bare feet. But most importantly for the historical origination of the random group design, in these transfer of training studies the design of the threshold experiments had to be adapted. Once the stimuli had

Figure 1 'Aesthesiometers' for pinpricks experiments. The one with three pins was especially designed for experiments with control trials (from Schulze, R., 1913. Aus der Werkstatt der experimentellen Psychologie und Pädagogik [From the workshop of experimental psychology and pedagogy]. Vogtländer Verlag, Leipzig, Germany.)

become trainings the original design of S-R-*noS*-R-S-R-S-R-*noS*-R-S-R-*noS*-R-S-R-S-R (etc.) was no longer feasible. Trainings cannot vary randomly as they cannot be haphazardly undone. Thus the standard design was limited to a particular 'cutout': (*noS*-) R-S-R. First a response (now an ability) was tested *without* preceding stimulus (now a training), next the training was given, and subsequently the ability was tested again. The transfer of training researchers worked with experimental groups whose abilities were compared before and after training.

Experimentation in Twentieth-Century Educational Psychology

While psychophysical experimenters were absorbed in their painstaking experiments, the world outside the laboratories was rapidly changing. In early-twentieth-century Western countries, the common ideology of *laissez-faire* politics was widely replaced by that of planned social progress. Social amelioration gradually turned from a local charity matter into a concern of centralized government. The concomitant emergence of bureaucratic administration was to generate significant changes in the kind of knowledge about human functioning and human relations that was produced.

Whereas the authority of nineteenth-century local officials depended on their personal trustworthiness, the newly appointed administrators had to justify their decisions in terms of impersonal data and overt standards. Moreover, progress had to come about as economically as possible. The expanding class of bureaucratic officials turned to professional social researchers for knowledge that could serve the needs of administrative standardization and efficiency. With the shift from aristocratic to bureaucratic domination the former gentleman-scholar trying to discover the given laws of nature was increasingly replaced by the administrative researcher looking for technically useful data (Danziger, 1990; Ross, 1991; Porter, 1995).

As far as psychology was concerned, the change was first brought about by psychophysical researchers taking an interest in educational administration. Around the turn of the twentieth century a debate blew up within American educational administrative circles on the utility of teaching subjects such as Latin and formal mathematics. School administrators wanted to abolish such subjects because of their apparent redundancy while proponents argued that 'formal discipline' strengthens general mental capacities. The issue reminded some American psychologists of the transfer of training phenomenon. Reasoning that formal discipline basically is a matter of transfer, they slightly adapted the former transfer experiments. They let subjects estimate weights or mark misspelled words, then trained them in estimating other weights or marking other misspelled words, and subsequently subjected them to the first tests again (*NoS*-R-S-R).

It may seem odd from a present-day perspective, but at the time a great deal of value was ascribed to the outcomes of such experiments. They seemed to provide an ideal basis for solid and impersonal decision-making. In the heat of the debate charges of experimental bias were soon made. In 1907, John E. Coover, a psychology student and former school principal, published an article on the issue (together with his teacher Frank Angell). The article argued that no valid causal conclusions can be drawn if the usual design of test-training-test (*noS*-R-S-R) was used (Coover and Angell, 1907). With this strategy, the authors emphasized, it is impossible to tell whether the outcomes are caused by the training or by any other factor. The first test, for instance, might serve as a training too.

In experiments done for Coover's 1905 master's thesis, and described in the 1907 article, the solution was used of comparing 'experimental reagents,' who had been given a training, with 'control reagents,' who had not. With Coover's design the usual sequence of (*noS*-) R-S-R was, so to speak, cut in two. The experimental group underwent the second part of S-R (training and test) and the control group only the first half of (*noS*-) R (a test without preceding training). In other words, the classical control *trial* in which the stimulus was withheld (*noS*), was now applied to special control *subjects* (more on the early introduction of the control group is given in Dehue, 2000)

Creating Equal Groups

In the 1910s, experimental educational research began to thrive. Educational experimenters acquired contracts from school administrators and left their laboratories for experimentation in real schools. 'Treatments' to be assessed now included methods of memorizing, ways of teaching, educational measures such as punishing and praising, and all kinds of classroom circumstances. The idea of using a control group also spread. In the 1916 volume of the *Journal of Educational Psychology*, 14% of the articles reported the use of control groups (Danziger, 1990: pp. 113–15).

In the schools, however, life was much messier than in the former locations of psychophysical experimentation. It was much harder to protect experimental results against charges of arbitrariness. Methodological scrutiny became ever more important. It soon turned out that a price had to be paid for comparing the results of groups rather than comparing subjects to themselves. Contaminating factors between the pretest and the post-test were replaced by invalidating differences between the groups.

At first it became customary to handle the new problem by hypothesizing which factors could bias the results, then subjecting subjects to preliminary tests for these factors, and next forming groups with equal test results. For instance, for testing the efficacy of a new way of teaching, equal groups were created by first measuring the pupils' intelligence and next composing equal groups as to mental capacity. With this 'matching' procedure, however, the choice of suspect factors depended very much on the researchers' personal imagination. Possibly the sex of the children also makes a difference, or their social background, or any other factor. Moreover, matching was very time and money consuming. For the combined reasons of saving money and cancelling out subjectivity – the twin principles of administrative rationality – experimental psychologists again invoked the methodological use of chance.

In 1923, the American psychologist William McCall published a manual entitled *How to Experiment in Education*. In his introduction, McCall estimated that increased efficiency in education could save a full year of teaching per person, and worked out that psychological experimentation would save '$134 680 000 000 000 for the next 100 generations of Americans.' He then he advanced a way of making his profession even more profitable to society, which was to compose the

groups by chance. McCall did not take the task of randomization lightly. He rejected the procedure of writing numbers on pieces of paper, because papers with larger numbers contain more ink and are therefore likely to sink further to the bottom of a container. He nevertheless maintained that 'any device which will make the selection truly random is satisfactory' (McCall, 1923: pp. 41–2).

Randomization, formerly used for creating random orders of stimuli, was now advanced as a cheap way of discarding unwanted differences between experimental groups. The random group design was first worked out in US educational psychology in the 1920s (on its later introduction in medicine, see Marks, 1997).

A Guiding Rather Than Practicable Principle

While most psychology textbooks ascribe the random group design to natural science, some credit the British biometrician Ronald Fisher with it. Fisher developed the design in the 1930s for agricultural research. His methodological handbook, *The Design of Experiments* (1935), was widely received indeed. However, psychologists did not learn to use randomly composed groups from Fisher. From the 1920s onwards, educational experimenters had struggled with the complexity of data resulting from experiments simultaneously testing various experimental groups and comparing them to one control group. Fisher offered statistical techniques for analyzing such complex between-groups variance and assessing the significance of the results (on Fisher's influence on psychology, see Gigerenzer and Murray, 1987). His warnings that, for *statistical* reasons, these techniques could only be validly used if the groups were randomly composed added extra authority to psychologists already promoting the employment of random groups. In the 1940s, a range of handbooks on research design and statistics, mostly written by educational psychologists, passed on Fisher's instructions to other branches of psychology. One of these methodological professionals was Quinn McNemar who would later observe that Fisher's ways quickly 'became epidemic just as though psychologists had never previously planned an experiment' (McNemar, 1960: p. 297).

At first, the combination of the random group design and significance testing seemed to provide an unquestionable experimental paradigm. Yet, in the context of experiments with humans, comparing random groups became an ideal mostly in the sense of a guiding principle rather than a viable strategy. Moral, legal, or practical reasons often prohibit people being given a treatment purely on the basis of chance. For example, the educational effects of prizes cannot be investigated by granting them at random, and differences in ethnic backgrounds among schools cannot be cancelled out by creating new classes on the basis of chance. Moreover, psychologists became involved with administrative research projects outside their traditional domain. From the 1930s, they were enlisted by other social scientists to measure the educational effects of radio talks and movies on issues such as voting, immigration, bootlegging, or war. In such contexts, it became all the more difficult to let the assignment of individuals to treatments depend purely on chance.

Renowned experiments by the US Army constitute a telling example of the unfeasibility of random assignment even with adult subjects living under command in a similar way to schoolchildren. During the Second World War, the Army's 'Morale Division' was charged with improving the soldiers' spirit. A film series entitled *Why We Fight* was made, and the Division's experimental section, chiefly staffed with psychologists, was asked to investigate the films' efficacy. The plan to evaluate the efficacy of these movies with the help of randomly composed groups did not work, as most soldiers became suspicious when some of them were summoned to see a movie while others were not. Random assignment thus appeared to elicit an unexpected new kind of bias. Although upon pretesting the existing army units turned out to differ in many consequential respects, the units had to be used as experimental and control groups (Hovland, 1949; for a history see Buck, 1985).

After the war, the army experimenters were ensured of jobs at the best US universities (Herman, 1995: p. 137). They widely propagated the standards of proper experimentation. Methodological treatises began to appear still advancing the random group design as the paragon form of experiment, but simultaneously indicating that unlike subjects in agricultural experimentation, people often cannot be assigned haphazardly to experimental conditions. Alternative designs and accompanying statistical techniques were developed.

Among the first methodologists to write in this vein was the young psychologist Donald Campbell, who also started his career in the army as an attitude and propaganda researcher. With the assistance of the statistician Julian Stanley, Campbell published a chapter entitled 'Experimental and Quasi-Experimental Designs for Research on Teaching.' In 1966 the chapter was reprinted as a separate 83-page booklet with the briefer but more-embracing title of *Experimental and Quasi-Experimental Designs for Research* (Campbell and Stanley, 1966).

The book was the starting point of Campbell's career as a renowned methodologist of social science. In the decades to come, innumerable publications and thick textbooks on 'true' and 'quasi' experimental designs by Campbell and many other authors in America and Europe were to follow. These works testify to the lasting high regard but limited applicability of random group experiments as well as their sociotechnical inspiration. As one of them summarized these three aspects in a striking comparison: 'Most people after all do not drive around in Rolls Royces or Cadillacs, even if they represent some peak of automobile engineering perfection' (Bulmer, 1986: p. 170).

Abstract

'Experimenter artifacts' and 'subject artifacts' are uncontrolled systematic errors that can arise within the experimental situation. Experimenter artifacts can be classified as being noninteractional or interactional. Subject artifacts can result from demand characteristics within the experimental situation and from the motivations of the subjects themselves. While there are strategies for minimizing potential artifacts, experimenters must be mindful of ethical considerations.

'Experimenter artifacts' and 'subject artifacts' refer to systematic errors that can be attributed to uncontrolled experimenter and subject variables, respectively. The term 'experimenter' is used broadly in this context to refer not just to scientists who perform laboratory experiments, but also to researchers working in any area of empirical investigation involving humans. Discussed here are the definition and history of artifacts in the social and behavioral sciences, the nature and control of experimenter and subject artifacts, a meditational model for conceptualizing how artifacts can be introduced into an investigation, and the delicate balance between ethical accountability and the avoidance of artifacts in research with human subjects.

The Nature of Artifacts in Scientific Inquiry

The sociologist H. H. Hyman wisely cautioned researchers not to equate ignorance of error with lack of error. Because all scientific investigation is subject to error, it is prudent to be aware of this, to expose the sources in an attempt to control them, and to estimate the magnitude of such errors when they occur (Hyman, 1954). In the social and behavioral sciences, researchers study the conduct of participants (or 'subjects') to further our understanding of the complexities of human behavior. Some of the complexity of subjects' behavior, however, results from specifiable but uncontrolled extraneous variables, often social in nature. The effects of such variables are conceptualized as a set of systematic errors (or 'artifacts') to be isolated, quantified, taken into account when interpreting the results, and, when possible, eliminated. Thus, artifacts not only are inconsequential effects in the research design, but also may jeopardize the validity of the results. To be sure, today's artifact could become tomorrow's independent variable, as conditions discounted as 'nuisance' variables at one time may be redefined as substantive variables in their own right in some future study. For example, the placebo effect in medical research, where an inert substance or nonspecific treatment produces a 'healing' effect, can be defined as an artifact but can also be exploited as a potential 'treatment' for chronic pain disorder (Turner et al., 1994).

Experimenter and subject artifacts, because they are conceptualized as systematic errors, are further distinguished from random errors. To explain the difference, Rosnow and Rosenthal (1997) envisioned an imaginary grocer who weighed the same bunch of grapes a number of times in a row. In an ideal world, no matter how precise the measurements, they would always come out a bit differently. Some measurements would slightly overestimate the correct weight of the grapes, while others would slightly underestimate the correct weight. Because the various overestimates and underestimates occur haphazardly (rather than in a patterned fashion), we can assume that the random fluctuations (or random errors) will cancel one another over the long run. Thus, we can simply average the measurements to estimate the correct weight of the grapes. But suppose the grocer always weighed the grapes with his thumb on the scale, thereby introducing a systematic error by always tacking on a few extra ounces to the true weight. This is essentially the nature of artifacts, inasmuch as they tend to push measurements in the same direction, up or down, systematically causing the 'average value' be consistently too large or too small. The problem for researchers is to determine the direction in which a particular artifact might push the results, to try to improve the accuracy of the measurements, and, when possible, to eliminate the source of systematic error and therefore the artifact.

The discovery of artifacts in the social and behavioral sciences has a long history, but it was not until the 1950s and 1960s that investigation of experimenter and subject artifacts began in earnest (see Rosnow, 1981, for a detailed discussion of the historical context and wider implications of this work). Claims about the existence of experimenter and subject artifacts were sometimes met with skepticism, but by the late 1960s there was ample evidence to show the magnitude of the artifact problem in social and behavioral research (see Rosenthal and Rosnow, 1969). Seminal investigations conducted by R. Rosenthal and M. T. Orne, working independently of one another, provided the initial impetus behind a flood of relevant work in the 1960s and 1970s. On the assumption that typical subjects often try to penetrate the nature of the study in which they are participating, Orne proposed the expression "demand characteristics of the experiment," which he derived from K. Lewin's concept of *Aufforderungscharaktere* to describe the 'demand value' of uncontrolled task-orienting cues in an experiment that exert an influence on subjects' ideas about its purpose. About the same time, Rosenthal showed that the

experimenter's tacit hypothesis or expectancy can sometimes become a self-fulfilling prophecy of the subjects' experimental responses. Well before this work appeared, however, there had been intriguing clues about the possible existence of artifacts caused by uncontrolled variables when sentient subjects are the objects of investigation.

Earlier Clues about Artifacts

An early indication about artifacts may be lurking in the investigative procedures used in animal research involving a horse named 'Clever Hans.' At the turn of the twentieth century, an eminent German psychologist, O. Pfungst (1911), carried out a six-week investigation of this remarkable horse owned by a mathematics teacher named von Osten. Hans, who responded by tapping his hoof according to a code taught to him by von Osten, was purported to be able to reason and answer questions put to him in German, including solving arithmetic problems. It was unlikely that von Osten had fraudulent intent because he readily allowed others (even in his absence) to question Hans, and also did not profit financially from the horse's talents. Thus, it was possible to rule out intentional cues from von Osten as the reason for the horse's cleverness. In a series of elegant experiments, Pfungst demonstrated that Hans's accuracy diminished when (1) Hans was fitted with blinders, so he could not see his questioners; (2) the distance between Hans and his questioners was increased; or (3) the questioner did not know the answer. These results implied that Hans's performance was due to something other than his capacity to reason. Pfungst found that Hans was responding to subtle cues given by his questioners, not just intentional cues but also unwitting movements and mannerisms. This classic research provided an object lesson in the susceptibility of behavior (even animal behavior) to unconscious suggestion.

A half century later, another influential development fostered the suspicion that human subjects behave in special ways when they know they are the 'subjects' of investigation. This proposition, called the 'Hawthorne effect,' grew out of a series of human factors experiments begun in the 1920s by a group of industrial researchers at the Hawthorne works of the Western Electric Company in Cicero, Illinois (Roethlisberger and Dickson, 1939). The experiments were intended to study how workers' productivity and job satisfaction might be affected by specific workplace conditions (light, temperature, rest periods, etc.). The conclusion reached, however, was that increases in productivity were due not to the manipulated experimental conditions, but to the uncontrolled effects of being singled out for participation and the adventitious cues intrinsic in the experimental situation. This research has subsequently been taken to task because of ambiguities and irregularities that make it difficult to interpret. It is also charged that secondary accounts of the research were tarnished by sweeping generalizations embroidered by overly zealous authors (for an interesting behavioral interpretation of previously unreported circumstances of the Hawthorne research, see, e.g., Gillespie, 1988; Parsons, 1974). Nonetheless, the 'Hawthorne effect' entered into the vocabulary of the social and behavioral sciences as implying a kind of placebo effect (see Sommer, 1968). As a consequence, researchers were advised to employ 'Hawthorne control groups,' which received special attention for a meaningless task. Presumably, by examining obtained differences in performances between the Hawthorne control group and a no-treatment control group, any Hawthorne effects should be detectable.

Another important development, which went largely unnoticed for many years, involved a conceptual advance. Rosenzweig (1933) published an insightful critique of uncontrolled aspects of psychology experiments. In particular, he identified three distinct sources of artifacts, which he theorized were associated with (1) the experimenter's 'observational attitude,' (2) the subjects' motivational states, and (3) the experimenter's demeanor when interacting with the subjects. Rosenzweig sketched procedures that he thought might obviate these 'errors,' such as the use of 'simple deceptions' to distract subjects from the true purpose of the experiment. He cautioned, however, that it might be unclear whether the experimenter or the subject was the 'true deceiver,' because subjects typically carry on a train of thought in which they attempt to guess the purpose of the experiment, and then model their behavior accordingly. Interestingly, early psychologists referred to their subjects as 'reagents,' implying that they resembled the ingredients that chemists mixed in clean test tubes to produce predictable reactions. Rosenzweig argued that the 'test tubes' (i.e., research settings) and 'reagents' (the subjects) of psychological researchers were sullied by the needs, anxieties, self-deceptions, and intentions of human beings who knew very well that their behavior was being scrutinized as part of a scientific investigation.

The Role of Experimenter Artifacts

Rosenthal (1966) divided experimenter artifacts into two general classes, called 'noninteractional' and 'interactional.' Noninteractional artifacts operate, so to speak, in the mind, in the eye, or in the hand of the scientist, but do not directly affect the subjects' responses. Within this class are three subtypes, known as observer, interpreter, and intentional effects. 'Observer effects' refer to overestimates or underestimates of results during the observation and recording phase of an experiment, which are controlled by the use of mechanical recording devices or by independent replications to discover if similar results are observed. 'Interpreter bias' refers to an error in the interpretation of data, which is ostensibly controlled by allowing other scientists to analyze and interpret the original data for themselves (see also MacCoun, 1998). 'Intentional effects' imply that the data were fabricated or fraudulently manipulated. Such distortions are devastating to science because they undermine the integrity of the literature on which the advancement of science depends; safeguarding against dishonesty is presumed to be the ethical responsibility of every scientist (cf. Carey, 2011).

Interactional artifacts, the second general class, are those due to extraneous experimenter-related variables that can directly influence the reactions of the research subjects. These include 'biosocial effects' (biases due to biological or social attributes of the researchers, such as the sex, age, ethnicity, and race of the researcher), 'psychosocial effects' (e.g., the

researcher's personality and comportment), 'situational effects' (biases attributable to uncontrolled aspects of the setting), and modeling effects (i.e., the example set by the investigator in the role of a 'scientist'). Replications across settings, subjects, and experimenters are used to isolate interactional artifacts, although procedural and sampling differences may not be easy to interpret. Moreover, scientists, like all humans, are susceptible to the biases imposed by the limitations of perception and cognition.

One additional interactional effect, well known in the social and behavioral sciences, was named the 'experimenter expectancy effect' by Rosenthal, its discoverer. It has spawned a large number of studies (Rosenthal and Rubin, 1978), with various applications in education, the law, and clinical practice (see Blanck, 1993). An 'experimenter expectancy bias' means that the experimenter's hypothesis leads unintentionally to behavior toward the subjects that, in turn, increases the likelihood that the hypothesis will be confirmed (reminiscent of the Clever Hans phenomenon). One solution to this problem is to keep experimenters unaware of ('blind' to) which subjects are to receive the experimental treatment and which the control treatment. If the experimenters do not know what treatment the subject has received, then they cannot accurately communicate expectancies about the nature of the particular treatment. The necessity of keeping experimenters blind is well recognized in randomized drug trials, for example. In fact, no drug trial is taken completely seriously unless it has followed elaborate 'double-blind procedures,' in which neither the subjects nor the experimenters know who is in the experimental group and who is in the control group.

The Role of Subject Artifacts

In focusing on subject artifacts, researchers have generally been interested in the role of motivations that guide the research subject's behavior. Orne (1962) described the role of the 'good subject,' that is, the participant who is particularly attentive to, and compliant with, demand characteristics. In one fascinating demonstration study, Orne asked subjects to add hundreds of thousands of two-digit numbers – which they kept doing until finally the experimenter gave up! Even when subjects were told to tear each worksheet into a minimum of 32 pieces before going on to the next, they persisted. Orne explained this behavior as the 'role enactment' of individuals who reason that, no matter how trivial and inane the assigned task seemed to them, it must have some important scientific purpose or they would not have been asked to participate in the first place. Thus, Orne argued, they complied with the demand characteristics of the experiment in order to 'further the cause of science.'

Not all research participants are willing to play the 'good subject' role, but Rosenthal and Rosnow (1975) reported that many volunteers for research participation are likely to conform to this expectation. Volunteers for research are also usually better educated, higher in social class status, more intelligent, more approval motivated, and more sociable than nonvolunteers. These and other demographics and personality characteristics may result in a 'volunteer subject bias' in that the results of studies using subjects who specifically volunteered may not be simply generalizable to the population at large. For example, standardizing the norms of an intelligence test on typical volunteer subjects may produce biased estimates of true values in a more general population. Rosenthal and Rosnow described some strategies for improving recruitment procedures and the generalizability of results, and also logical procedures for estimating the direction of volunteer subject bias.

Other subject motivations may be operating, however, including what Rosenberg called 'evaluation apprehension,' referring to an anxiety-toned state in which subjects worry that the experimenter plans to evaluate an aspect of their psychological competence. As a result, they develop their own hypotheses about how to win the experimenter's approval or avoid disapproval. Experiments in which evaluation apprehension appears likely to occur are those that contain an element of surprise or have an aura of mystery. The more transparent and salient the task-orienting cues and the more control the experimenter has in administering a positive or negative evaluation, the greater may be the bias ostensibly resulting from the participant's evaluation apprehension (see Rosenberg's discussion in Rosenthal and Rosnow, 1969). One solution to this problem is to ensure the confidentiality of subjects' responses, on the assumption that individual subjects will be less apprehensive and more forthcoming in their responses. In research on sensitive topics, such as studies of sexual behavior, self-reported data nevertheless may be suspected of measurement error and participation bias (for a detailed discussion, see Cantania et al., 1990).

Other subject artifacts have been studied in the field of assessment, including a variation on evaluation apprehension known as 'social desirability bias.' In this case, the respondent to a personality inventory answers items in ways that seem to elicit favorable evaluations. One way to assess this problem is by means of a questionnaire that was specifically designed to tease out this response bias (Crowne and Marlow, 1964). Various other subject biases in assessment have been identified, and particular strategies have been developed to isolate or avoid those problems, such as the development of 'lie scales' to detect prevarication.

Minimizing Potential Artifacts

In his discussion of the social psychology of the experiment, Strohmetz (2008) described a meditational model earlier proposed by Rosnow for conceptualizing how artifacts may be introduced into an investigation. The first step is the degree to which subjects are receptive to the presence of potential demand characteristics in the experimental situation. These demand characteristics could stem from the methodology itself or from the experimenter present in the situation. The second step concerns the motivation of subjects to act upon these task-orienting cues. Volunteer subjects as well as those experiencing evaluation apprehension may be particularly motivated to alter their behaviors in response to perceived demand characteristics. The last step involves the capability of subjects to alter their behavior in response to the demand characteristics. Allen (2004) provided empirical support for the receptivity and motivation steps in this model.

The utility of this model is that it suggests opportunities for experimenters to identify and therefore minimize the potential for artifacts that can threaten the internal validity of a study and its conclusions. For example, experimenters could reduce receptivity by using deception to divert subjects' attention away from potential task-orienting cues. Interactions between the experimenter and subjects can be limited to control this source of demand characteristics. Conducting studies in naturalistic settings and utilizing unobtrusive measures can reduce the likelihood that the subjects are aware that they are being observed, making them less receptive to the presence of demand characteristics. Reducing subjects' motivation to act upon potential task-orienting cues can also reduce the potential for research artifacts. To minimize a volunteer bias, experimenters can implement inclusive strategies for recruiting research participants. Employing nonthreatening procedures can help reduce evaluation apprehension and social desirability concerns.

While this model is a useful heuristic when designing an empirical study, there is no assurance that artifacts have not been introduced into one's study. Orne (see his chapter in Rosenthal and Rosnow, 1969) suggested a strategy to ferret out potential demand characteristics by using 'quasi-control subjects' in addition to the usual control groups. Quasi-controls are individuals who are asked to step out of the traditional subject role; they reflect on the experiment in which they participated and suggest how their own experimental behavior was influenced by extraneous variables as opposed to only the controlled independent variable. It is now argued, however, that demand characteristics also exert influence on behavior beyond the experimental setting and should be recognized as a pervasive influence on all human interaction (for the role of demand characteristics in the context of psychotherapy, see Orne and Bauer-Manley, 1991).

Artifacts and Ethics in Collision

Until World War II, the popular conception of science as an 'endless frontier' unencumbered by moral constraints remained largely unshaken. Currently, however, investigators in even the most benign areas of the social and behavioral sciences are required to comply with stringent ethical guidelines laid done in professional and statutory codes overseen by review boards (see Rosnow et al., 1993). This situation can at times lead to knotty moral dilemmas as researchers try to strike a balance between ethical accountability and the technical demands of sound scientific practice (see Blanck et al., 1992; Kimmel, 1996). The effort to control for artifacts may, for example, come into collision with ethical imperatives such as informed consent and full disclosure. By way of illustration, in clinical trials using double-blind designs in which the control group is given a placebo, complying with full disclosure implies that the potential participants will be told they could be in a condition that will be deprived of possible benefits of the experimental treatment. Once they become aware of this fact, however, some subjects might surreptitiously share doses in the hope that this will increase the likelihood that each of them will receive at least some access to the experimental treatment. Such a situation could render any subsequent comparison of the experimental group and the 'untreated' control group meaningless. A strategy that can be used to avoid this problem, if there is an alternative treatment that is better than a placebo, is to provide the control group with this treatment rather than a placebo. This approach avoids the ethical bind of depriving control patients of any effective treatment, keeps the design double-blind, and focuses the research on other comparisons of practical and scientific importance (e.g., efficacy, relative cost, and side effects). As moral dilemmas proliferate in the sciences, the challenge faced by researchers is to expand our existing knowledge with valid data and yet abide by an evolving social contract that is responsive to current ethical sensitivities (for further discussion, see Rosnow, 1997).

Experiment in Science and Technology Studies

Abstract

'Experiment' is a category of study that has long stood at the heart of much work in science and technology studies. Its meaning, however, has changed over time, depending upon the overall analytical setting within which it has been invoked and provided with its significance for the understanding of science. This article follows the development of ideas about 'experiment' from its role in the mainstream Anglo-American philosophy of science of the 1950s and 1960s through to its reconsideration in the sociologically oriented work of the 1970s and 1980s, until its new, nuanced place in the understandings of science as practice and process that were developed during the late 1980s and throughout the 1990s.

Experiment was a major concern of science and technology studies (STS) during the last quarter of the twentieth century. This is because certain views of experimentation as a privileged way of making knowledge about nature were important focuses of dissent during the specialty's early career. Various versions of the so-called 'received view' of science prevalent in Anglo-American philosophy of science in the period following World War II, with their roots in logical empiricism, held up experiments as the crucial empirical elements of scientific knowledge. Irrespective of whether the logic employed in their modeling of scientific reasoning was falsificationist or conformationist, versions of the 'received view' represented theories as conceptual structures that coordinate with the world through independent experimental tests of their predictions. This article will survey some of the major developments that have emerged to modify those older views.

Development of New Approaches to Experiment: Challenges to the 'Received View'

In the 1950s and early 1960s, one of the central assumptions of the 'received view' was seriously challenged. The presumed independence of experimental and observational data from contamination by the very theories that the data were intended to judge was challenged by W.V.O. Quine (Quine, 1953), Norwood Russell Hanson (Hanson, 1958), and Thomas S. Kuhn (Kuhn, 1970 [1962]). Quine showed, using an argument similar to one used by Pierre Duhem (1954), early in the twentieth century, that empirical data always underdetermine the theories that can rest upon them. In Duhem's hands, the argument rested on a position of 'conventionalism,' whereby the relationship between items of discrete empirical data and the theories employing those data was seen to be underdetermined; in particular, Duhem argued that there could be no such thing as a 'crucial experiment' that could decide definitively between two alternative theories. A result inconsistent with one of the theories need not be attributed to an inadequacy in the target theory itself, but might instead be attributed to error in a subsidiary theory (such as one relating to observational instruments) that had not initially been in question. Possibilities of that sort amounted to decisions, according to Duhem, and were consistent with a conventionalist view of scientific theories, whereby pure convention determined which in a network of theories would be preserved and which amended so as to fit experimental results.

Hanson and Kuhn went further, with their arguments in favor of the 'theory-ladenness of observation.' They held that a pure observation language was in principle impossible, and that, accordingly, the results of experiments and observations of nature always implicated theoretical concepts in their very formulation. This position blurred the distinction between empirical data on the one hand and the theories that are justified by those data on the other. Both Kuhn and Hanson likened empirical data to the psychologist's gestalt experiments, wherein, for example, the 'same' image can sometimes be seen as a duck and sometimes as a rabbit; the difference, they claimed, was that in science there is no possibility of resting one's description on an account of the underlying set of lines. Instead, the scientist sees a duck or a rabbit, with no further reduction to a common observational base being possible. All empirical data are already interpreted; that is, seen in a particular way (cf Fleck, 1979 [1935], an acknowledged source for Kuhn).

Sociological and Historical Exploitations of New Theoretical Arguments

These challenges to the 'received view' of science provoked much debate in the 1960s and into the 1970s. In its wake, however, there arose attempts to exploit ideas of such as those of Hanson and Kuhn in the service of sociological projects aimed at making sense of scientific knowledge as a social product. In the early days of the 'sociology of scientific knowledge' (SSK), the Duhem–Quine 'underdetermination' thesis became a standard in-principle justification for sociological studies of the acceptance of knowledge claims by scientific communities (e.g., Mulkay, 1979; Knorr-Cetina and Mulkay, 1983). This was so because it was argued that the inadequacy of empirical evidence to necessitate belief in any particular theory in science left room for social explanations for which belief among the manifold logical possibilities was actually chosen. At the same time, however, a more fundamental theoretical challenge to the self-sufficiency of 'received view' accounts of the role of experiment in science was being developed by H.M. Collins, drawing on a sociological reading of Wittgenstein (Winch, 1958; cf Bloor, 1983).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85006-0

Wittgenstein had argued that rules do not contain rules for their own application; such a position, in the form of 'finitism,' also applies to practices of classification (see, for a summary of its relevance to STS, Barnes et al., 1996). The basic claim amounts to observing that every new situation, every new occurrence of some kind of event, is in its own way unique; it therefore requires indeterminate judgments of similarity and difference to decide whether a new event or instance is or is not a legitimate member of a given category. In articles from the mid-1970s onward, and culminating in a book in 1985 (Collins, 1985), Collins developed empirical case studies that exploited Wittgenstein's arguments to show how the participants in actual scientific controversies resolve problems of the ambiguity of experimental outcomes. In work on claims to the detection of high-flux gravitational radiation in the 1970s, as well as in the transfer of skills relating to the successful replication of transversely excited atmospheric (TEA)-laser technology, Collins developed the notion of the 'experimenters' regress,' which he saw as an application in the domain of the sociology of science of Wittgenstein's 'indeterminacy of rules.' In the case of an experimental result, a judgment must be made that involves deciding whether the experiment or experimental run was competently conducted. If yes, then the outcome can be used to assess an associated theoretical claim (which would then open up Duhem–Quine issues), whereas if not, then the outcome will be irrelevant to the claim. Collins showed that, routinely, such assessments of experimental competence were central to scientific controversies. The ultimate criterion for judging the competence of an experiment, according to Collins, was whether the experimental outcome was correct or not. In the case of experiments, the results of which were taken to depend on unknown or controversial aspects of the natural world, therefore, controversy over nature was coextensive with controversy over which experiments were fit to be taken into account in reference to that feature of nature. This, then, is the essential paradox designated by the term 'experimenters' regress': it is only possible to know whether an experiment was competently performed if it is known what the correct outcome should be, but (in an empiricist epistemology) the correct outcome can only be known as a consequence of the performance of competent experiments.

The sort of empirical studies of scientific practice conducted by Collins also yielded fruitfully to analysis in terms of the Duhem–Quine thesis. Trevor Pinch's 'Towards an Analysis of Scientific Observation' (Pinch, 1985) introduced the idea of 'externality' in understanding the role and fate within the scientific community of experimental work. Pinch noted that knowledge-claims made on the basis of experimental studies could themselves be couched in alternative ways that maximized or minimized the likelihood that the competence and reliability of the experiments themselves would be questioned. An experimentally based assertion with high externality would be one that used the experimental outcome to make far-reaching inferences about some domain of existing knowledge; an assertion with low externality would depart but little from a bald statement of the local circumstances of the experimental situation, and could provoke but little controversy. Andrew Pickering (1984) examined similar professional dynamics in the theoretical and experimental work in particle physics that established the existence and characteristics of quarks in the 1970s.

Together, the Duhem–Quine thesis, finitism, and the experimenters' regress had opened up, by the mid-1980s, a vast terrain within which sociologically informed study of the experimental dimensions of scientific knowledge could be conducted. A landmark study that fully exploited the new possibilities was Steven Shapin and Simon Schaffer's *Leviathan and the Air-Pump* (Shapin and Schaffer, 1985/2011). This historical study directly challenged the older 'received view' of the role of experiment in making scientific knowledge, and did so by investigating a classic, oft-cited historical example usually held to exemplify that view. The subject chosen in the book was the air-pump work of Robert Boyle in the 1660s. Boyle's work had been presented (Conant, 1970 [1957]) in one of the *Harvard Case Histories in Experimental Science*, dating from the late 1940s and 1950s. These were publications that, importantly, had shaped the teaching and scholarship in the history of science for many years, and which were consistent with the usual conception of experiments as unequivocal arbiters of theoretical ideas. Shapin and Schaffer thus accepted Boyle's air-pump experiments, for the sake of argument, as an exemplary model of scientific procedure. They then attempted to show how a close examination revealed that Boyle's experiments and their associated knowledge claims were far from unequivocal – were, in fact, strongly contested – and that the interpretation of them advanced by Boyle and his allies could also be understood as part of a political vision of the proper social constitution and conduct of a philosophical community. In order to achieve this purpose, Shapin and Schaffer used the criticisms of Boyle advanced by the philosopher and mathematician Thomas Hobbes, a man whose view of the proper way to make natural knowledge differed significantly from that of Boyle and whose associated conception of the place and legitimacy of knowledge in a polity also differed markedly from Boyle's. Hobbes's detailed criticisms of Boyle's air-pump work revealed an alternative set of values and commitments regarding the best way to achieve social stability and consensus, a way that invalidated experimental work as an effective means of securing knowledge claims. An alternative approach to similar issues (Dear, 1985, 1987, 1995) focuses on conventions of knowledge making that were less local than those examined by Shapin and Schaffer, and which support a view of much more mediated connections with social organization. Dear's main argument is that the modern 'experiment' as a historically specific, contrived event was a development of seventeenth-century Europe, and had close filiations with disciplinary approaches employed in mathematical sciences that stressed operationalism.

Laboratory Studies and Naturalistic Approaches

By the mid-1980s, in addition to the work already discussed, a number of so-called laboratory studies were being published. These studies also had a strong influence on views of experiment in science, but, in contrast to the approaches considered above, they tended to eschew, often explicitly, an overt engagement with the 'received view' philosophies of science. Instead, the methodological and/or epistemological

approaches that were central to laboratory studies drew from such traditions as those of anthropology, ethnomethodology, and phenomenology. The three crucial and exemplary lab studies from this period were Latour and Woolgar's *Laboratory Life* (Latour and Woolgar, 1979), Karin Knorr-Cetina's *The Manufacture of Knowledge* (Knorr-Cetina, 1981), and Michael Lynch's *Art and Artifact in Laboratory Science* (Lynch, 1985). These three have in common a naturalistic stance toward the work of the laboratory, rejecting presuppositions as to the character of that work. Thus, they have no a priori interest in studying laboratory work as a means of learning how 'reliable,' or 'true,' or 'epistemologically privileged' knowledge results from laboratory practices. Instead, they treat their particular laboratories as sites where activities are carried out, and attempt to describe and account for the nature of those activities. A notable feature of the rapidly changing intellectual landscape on which these laboratory studies were performed is the existence, in the first edition of *Laboratory Life*, of the subtitle *The Social Construction of Scientific Facts* (Latour and Woolgar, 1979), and its replacement in the second edition, by the less doctrinaire *The Construction of Scientific Facts* (Latour and Woogar, 1986). The change signals the way in which, in the years surrounding 1980, the rhetoric of SSK, with its insistence on 'social construction' as the crucial mechanism by which scientific knowledge was made, dominated science studies. By 1986, this insistence was already looking rather hackneyed and uninformative in some quarters.

The place of experiment in the tradition of laboratory studies is less clear-cut than it was in the mainstream SSK tradition, because the former were not reacting directly to the epistemological highlighting of experiment characteristic of the philosophical 'received view.' Thus, experiments were less likely to be seen as obviously individuated events; instead, they were seen as falling within an overall passage of scientific activity. The highlighting of particular experiments as especially significant cognitive elements of such passages now became contingent on the behavior and interactions of the scientists being studied, rather than being self-evidently central to an understanding of scientific work.

A collection of papers originating in a conference of 1985 on 'The Uses of Experiment' (Gooding et al., 1989; see also Le Grand, 1990 for a similar collection) attempted to shed light on experiment as a category used by scientists rather than as an epistemologically significant item singled out by philosophers. The contributors made use of the new work in science studies to lay out, chiefly by means of empirical studies of contemporary and past science, the multifarious ways in which experiment has been used as a rhetorical and practical tool in the establishment of knowledge-claims and in the consolidation of scientific communities of practice. One especially notable concept deployed in this volume, centrally in the contribution by Simon Schaffer (1989), was that of experimental 'transparency.' This concept designated situations in which an experimental apparatus becomes so unproblematic and theoretically unquestioned that the phenomena to which it affords access are seen directly, as it were, as if no theoretically justified experimental device intervened between observer and phenomena. In such cases, in effect, the apparatus has changed from being an experimental setup to being a scientific measuring instrument. For example, such was the fate of the mercury barometer in the seventeenth century, which began life as an experiment intended to examine the pressure of the air and the possibility of a vacuum but which, by the end of the century, had become an instrument for measuring atmospheric pressure as an aid to understanding the weather. These kinds of conceptualization also hark back to the much earlier work of the French philosopher Gaston Bachelard, who spoke of the artificial creation of phenomena by apparatus, using the term *phénoméno-technique* (e.g., Bachelard, 1938; see Gaukroger, 1976 for a lucid introduction).

The second half of the 1980s also saw the appearance of empirical studies of modern physical experimentation that adopted attitudes quite different from those of the advocates of SSK. Peter Galison, in his book *How Experiments End* (1987), examined several episodes in post-World War II high-energy physics in the United States. The book's intention was to describe the ways in which experimental closure was brought about in the episodes discussed, but in a way explicitly opposed to accounts given by Collins and Pickering, among others; that is, Galison's aim was to show that social mechanisms were insufficient to explain the outcome of the experimental work. Allan Franklin also published work on modern experimental physics with broadly the same aim (Franklin, 1986, 1990). In both cases, they aimed to stress the role of an independent physical world in creating sometimes-unexpected outcomes to experiments was emphasized, and (in Franklin's case, at least) to downplay the role of social actions and social structures in determining outcomes. Franklin argued that social considerations become irrelevant in light of the overwhelming influence of objective experimental outcomes and their correct rational assessment. Franklin's position, however, appears largely to ignore the epistemological problems that fueled SSK.

Discussions of experiments and the best ways of understanding their role in science also went well beyond issues of their direct epistemological function. Historical studies, preeminently Shapin and Schaffer's *Leviathan and the Air-Pump*, were by now having an impact on wider conceptions of the ideological structure and social meaning of science. The most important example of that impact was Yaron Ezrahi's (1990) *The Descent of Icarus*. This took Shapin and Schaffer's presentation of Robert Boyle's kind of experimental science as the model for science ever since the seventeenth century, and adapted their view of its political meaning to an account of the development of modern liberal ideology and, subsequently, modern liberal states from the eighteenth to the twentieth centuries. In Ezrahi's view, the legitimacy of experimental knowledge claims in science became the accepted norm for knowledge claims in the political arena as well. Shapin and Schaffer had stressed the role of 'witnessing' in Boyle's kind of experimental science, whereby many people, either directly or through the reading of detailed reports ('virtual witnessing'), came to attest the truth of an asserted experimental outcome and thereby its associated factual knowledge claim. Ezrahi suggested that a similar visibility, or transparency, of political actions and the reasons for them became the political ideal, along with the notion of the accountability

of political leaders. Ezrahi's ideal-type of such a polity, the United States in the twentieth century, thus placed great stress on the possibility of citizens seeing what their government was doing and in assessing the grounds for and wisdom of those actions (see also Latour, 1993 for different political extrapolations, with a focus on 'modernity' rather than specific nation states).

Latour on Experiments and Their Mobility

Other aspects of experimentation were also investigated in the 1980s and early 1990s, most notably in the work of Bruno Latour. Latour's naturalistic approach to scientific practice, which had been explicitly anthropological in inspiration in *Laboratory Life*, extended his representation there of laboratory science as an enterprise centrally concerned with the production of 'literary inscriptions' (any kind of trace inscribed on paper). This extension took the form, in his *Science in Action* (Latour, 1987), of an analysis of the structure of experimental papers. That structure, he argued, reveals the agonistic logic of experimental procedures through a kind of shadowboxing, whereby the paper's authors attempt to anticipate and head off skeptical criticisms of their claims, such as might be put forward by a determined opponent. Thus, the experimental paper/document (and, by implication, the experimental protocol itself) takes the form of one side of a dialog aimed at silencing the critic through anticipation of all plausible objections. Part of the power of this analytical approach supposedly resides in Latour's stress on semiotic analysis (Latour and Bastide, 1986), which connects with his emphasis on taking into account 'natural actants' in accounts of scientific activity (see also Latour, 1988). Thus semiotic actors in the experimental account, which are normally taken to refer to things in the natural world (such entities as subatomic particles, or microbes, etc.), are treated on a par with those semiotic actors normally taken to refer to things in the social world (preeminently, the scientists performing the experiment). Thus, they are understood in exactly the same way. Latour therefore claims that there is no justification for treating social actors as real while treating 'natural actors' as simply social constructs, which is what (in his view) the SSK approach advocates. Problems seem to arise in Latour's approach, however, when the question of shifting between the analytical level of the semiotic and the analytical level of the putatively 'real' is considered; Latour is obscure on the point.

One especially influential idea in Latour (1983, 1988) concerns a way of understanding how experimental outcomes can be mobile; that is, how a successful experiment conducted in a specific laboratory is made to be successful, or at least persuasive, at other locations. This issue has been referred to as the 'problem of constructivism' in Golinski (1998); although Latour would not count himself as a 'constructivist' in the SSK sense, his similar stress on the work that goes into creating an experimental 'fact' leaves him with the same problem. The difficulty that Latour purports to solve is to explain how, if experimental facts are made in situations whose specificity and locality ('natural' and 'social') are taken as crucial to explaining the particular outcome, that outcome is seen to be reproduced in significantly different settings. The traditional ('received view') answer is that the experimental outcome is simply a reflection of the way that nature works, and an implicit principle of the uniformity of nature therefore implies that the same experiment, in the sense of the same material setup and procedure, will yield the same result wherever it is conducted. The constructivist, however, because of a conviction that 'social' elements (however defined in detail) are essential to producing the outcome, appears to have difficulty in explaining this mobility of experiment (cf Collins, 1985 on the TEA-laser). Specifically, Latour explains the apparent paradox of experimental success outside the laboratory setting, using Louis Pasteur's field trials of his anthrax vaccine as an example, by denying that the laboratory has ever really been abandoned. Instead, when, for instance, Pasteur managed to create a vaccine found to work on animals in carefully controlled laboratory conditions, his demonstration of its effectiveness on actual farm animals involved, according to Latour, transferring his laboratory to the farm. It was not that Pasteur's vaccine worked in the laboratory and on the farm; the vaccine only ever worked in the context of the laboratory trial. Pasteur's trick lay in turning the farm into a laboratory while maintaining the illusion that it was still only a farm. Hence, experiments can be spread, on this view, only via networks of laboratories or laboratory-equivalents; they do not in fact work everywhere.

Experimental Systems

In the 1990s, there appeared a number of new conceptualizations of experiment, including an important collection of essays concerning the life sciences, *The Right Tools for the Job* (Clarke and Fujimura, 1992), and significant discussions of various experimental practices and regimes in Peter Galison's *Image and Logic* (Galison, 1997). These new conceptualizations had in common a more expansive and complex view of the ways in which experiment forms a part of elaborate systems of scientific practice. Andrew Pickering's *The Mangle of Practice* (Pickering, 1995) developed from and built upon his earlier SSK-influenced work by attempting to understand scientific practice as pragmatic interactions among experimental procedures, theoretical models, and physical reality. The resistance and accommodation arising through the interaction between these theoretical and material practices had become in Pickering's work an important and central feature that rejected any attempt at pure sociological reductionism (although whether this has ever truly existed in STS is a debated point). Pickering saw scientific work as an ongoing enterprise aimed at stabilization: theory and experiment cooperate, at least for a time, in producing mutually consistent, intelligible interactions between human beings and the world. By placing experiment within this more complex structure of scientific practice, Pickering thus endeavored to move beyond the sociological insights of science studies and to regain a connection with the natural (and obdurate) reality with which science has always claimed to deal.

Similar pragmatic moves had also appeared in an important study by the historian Robert Kohler. In his *Lords of the Fly* (Kohler, 1994), Kohler studied the early decades of *drosophila* (fruit-fly) research in the United States, centered on the laboratory of Thomas Hunt Morgan at Columbia University and subsequently at the California Institute of Technology. Kohler described the operations of Morgan's fly lab in terms of the exploitation of the capabilities of the materials, centrally including the flies, with their particular breeding and variation characteristics. The whole taken together, and crucially including material practices (given some precedence in this study over intellectual practices), was characterized by Kohler variously in terms of 'experimental practice,' 'experimental production,' or as a 'system of experimental mass production.' The term 'experimental system' was also used by Hans-Jörg Rheinberger in an ambitious study, *Toward a History of Epistemic Things* (Rheinberger, 1997). Rheinberger, following the same general tendencies as Kohler and others, and with an important nod to Fleck, represented his project as being directed against the old philosophical tendency to view experiments as isolated epistemological elements, instead focusing his attention on the integration of experiment within a multifaceted system of practices which together constitute the modern scientific enterprise (cf also Knorr-Cetina, 1999; especially pp. 39–43). Consequently, experiment has lost much of its former philosophical mystique.

The Disappearance of the Experiment from Science and Technology Studies

Although Collins (2004, 2011) has published further episodes in his long-term study of developments in gravity wave experiments, after the 1990s, there have been few, if any, major works in science and technology studies that explicitly treat 'the experiment' as a topic of investigation. A continued interest in scientific 'practice' (Schatzki et al., 2001) does not necessarily, as noted earlier, place 'the experiment' at its heart. In part, this decline of interest in the topic reflects a trend in the sciences themselves, away from 'pure' physics and toward biomedicine, information science, and hybrids of science and engineering (see Park Doing's, 2009 close ethnographic account of the ascendency of biologists at a facility once dominated by physicists). Studies of the relationship between laboratory practices and those of field sciences further illustrate the layered complexity that now typifies work involving experiment (Kohler, 2002). The relative lack of interest also reflects a move within science and technology studies toward the politics of science and questions about (as well as efforts to engender) public engagement with sciences. Particular agendas and multiple constituencies interact in, for example, agricultural field trials in which farmers tentatively allow scientists to conduct experiments in their fields (Henke, 2008). Other modes of 'impure science' (Epstein, 1996) are exemplified by clinical trials that involve agents and agendas from science, medicine, government, corporations, and social movements, which all have input into experimental designs and results. Such cases are of far greater current interest in science and technology studies than the classic mode of experimental practice. Nevertheless, the protocols and idioms of 'the experiment' are far from irrelevant. Even clinical trials can exhibit a highly creative mix of classical test and control conditions, together with ethical considerations, such as designing a cancer drug trial in a way that takes into account that it will be truncated as soon as evidence emerges of a likely beneficial effect of the tested combination of chemicals (Keating and Cambrosio, 2012).

Earlier research on experiments in history and social studies of science remains important, not perhaps as an explicit foundation for current research, but more as a resource that is invoked for arguing that the logics and practices of contemporary experiments are deeply intertwined with an entire array of social and cultural agents and agencies – logics and practices that do not adhere to the received view of experiment that prominent spokespersons for science, government officials, and even high court judges continue to use to legitimate and rationalize policies and decisions.

Abstract

Courts in civil and common law systems rely upon experts to help triers of fact render appropriate legal judgments. Expert testimony strongly influences evaluations of trial evidence and verdicts. Because expert testimony is so influential, the laws governing the admissibility of expert evidence are evolving. Despite the courts' best efforts to admit only unbiased and reliable expert evidence, judges may lack the skills and abilities necessary to accurately evaluate scientific methodology, and the adversarial nature of many legal systems may induce partisan bias in expert testimony. Therefore, court systems need procedural safeguards to help fact finders evaluate the quality of expert testimony.

To assist triers of fact in rendering appropriate legal judgments, courts may seek the assistance of experts. Courts admit expert testimony in legal proceedings when a judge or jury needs assistance evaluating a material fact in a court proceeding. Qualified by education, skill, or technical expertise, an expert provides fact finders with specialized information to educate them about case-relevant issues that are not within the common knowledge of the fact finder. Expert testimony differs from other types of testimony in legal proceedings because only experts may offer opinion testimony. As such, expert testimony is treated with care in the legal system.

Expert Testimony in Civil Law Systems

The primary distinction between the use of experts in civil and in common law systems is who retains the expert. Experts in civil law systems are generally called by the presiding judge as a court-appointed expert. Judges seek expert testimony when the issues to be resolved are beyond the understanding of the court. Judges may seek the opinion of one or multiple experts to answer a question. The expert may be required to conduct research to answer the question or may just be asked to provide known information that would help address the issue. Generally, the judge will provide a timeline for the expert to provide a written report that addresses the question posed to the expert. Upon the deadline, this report is delivered to the parties by the judge. Normally, there is no oral testimony of the expert unless the parties or the court call the expert to answer questions (Spencer, 1998). Although the general rule is that the judge will appoint an expert when necessary, parties may (but rarely do) call their own expert witnesses in civil law systems (Timmerbeil, 2003). However, when experts are appointed by a party rather than the court, they are often restricted from testifying and are only permitted to provide a written report (Timmerbeil, 2003).

Experts in the civil law system are often thought to be more neutral, more independent, and less biased than experts in common law systems because they are not accountable to any particular party or lawyer. However, judges in civil law systems also play a more active role in the adjudicative process. Thus, the judges in civil law jurisdictions are often viewed as less neutral than judges in common law jurisdictions, so there is some debate as to whether these experts are less biased than common law experts or just biased toward answering the judges' question in a manner that is consistent with the judges' opinion (see van Kampen, 2003).

Laws regarding the admissibility of expert testimony in civil law systems focus on the scope of the expert's duties and whether the expert's testimony or opinion is binding upon the presiding judge. For example, French courts maintain lists of experts who meet certain qualifications, although judges are free to appoint an expert who is not on the list (Taylor, 1996). In Korea and France, the findings of the expert are not binding upon the judge (Lee, 1997; Taylor, 1996).

Expert Testimony in Common Law Systems

In common law systems, it is typical for either party or both parties to proffer expert testimony. Much like civil law systems, judges also have the power to appoint court-appointed, neutral experts (Federal Rules of Evidence (FRE) 706); however, in practice, court-appointed experts are rare (Spencer, 1998). Because the parties' respective attorneys typically hire experts, experts in the common law system are often criticized for being hired guns. Indeed, attorneys may seek experts who will testify favorably with regard to their position, rather than providing testimony that is representative of the general scientific community. Further, experts are well paid in common law systems for their testimony.

In common law systems, judges must determine whether the testimony will be admitted into evidence. Each country in the common law system has its own unique laws regarding the admissibility of expert testimony, but there are several striking similarities across many of the countries, including the United States, Australia, England, and Canada (Gatowski et al., 1996). In each of these countries, judges may admit expert evidence only if it is relevant to a factual issue in contention and may admit expert evidence only if it will not confuse, mislead, or unfairly bias the jury. To be admitted at trial, the expert evidence must be able to assist the trier of fact in making a decision. If the expert evidence is within the common knowledge of the fact finder, then it should not be admitted. One concern with regard

to the admissibility of expert evidence is the reliability or scientific validity of the information that experts are providing in court. Court opinions in both the United States and Canada have addressed concerns about the proliferation of unreliable or junk science in court. These decisions have delineated specific criteria that judges must use to assess the reliability of expert evidence. Courts in England and Australia have not provided specific criteria for evaluating the reliability of expert evidence; however, they have ruled that expert evidence must be based on legitimate science or expertise (Gatowski et al., 1996).

Laws Governing the Admissibility of Expert Testimony in the United States

In the United States, expert testimony is required to meet certain criteria before being admitted into court. The purpose of these criteria is to ensure that unreliable expert testimony is prevented from entering the courtroom and influencing jurors' decisions. In 1923, federal courts evaluated scientific expert testimony on the general acceptance test, established in *Frye v. United States*, which specified that scientific evidence should be admitted if it is generally accepted within the relevant scientific community. This rule originated from a case in which James Frye was on trial for murder and his attorney wanted to present the results of a systolic blood pressure test, a predecessor to the polygraph, in support of his innocence. The trial court did not permit this testimony. Frye appealed and argued that the expert's testimony was improperly excluded. The District of Columbia (DC) Court of Appeals, however, agreed with the trial court and stated that because systolic blood pressure was not generally recognized as a method of lie detection within the scientific community, the trial court had met the appropriate grounds for exclusion. In essence, *Frye* placed the responsibility of evaluating the admissibility of expert testimony squarely on the shoulders of the relevant scientific community. Two main criticisms emerged from relying on *Frye*'s general acceptance test as the standard for admissibility. First, *Frye* excluded novel but valid research. Second, *Frye* was criticized for accepting invalid research that met the general acceptance test among a majority of researchers.

In the late 1960s, US Supreme Court Chief Justice Earl Warren and the US Congress worked together to create a series of new rules designed to help judges determine whether to admit evidence at trial, referred to as the FRE. The FRE included new rules governing the admissibility of expert testimony. These rules specify that expert evidence must be relevant to an issue in the trial (FRE 403), must not be within the common understanding of the juror, and must assist jurors with understanding a disputed issue in the trial (FRE 702). Further, in the Advisory Committee notes, the committee members specified that the rule is broadly written so as not to limit judges' evaluations 'merely to the scientific and technical but extend to all specialized knowledge. Similarly, the expert is viewed, not in a narrow sense, but as a person qualified by knowledge, skill, experience, training or education. Thus, within the scope of the rule are not only experts in the strictest sense of the word, e.g., physicians, physicists, and architects, but also the large group sometimes called skilled witnesses, such as bankers or landowners testifying to land values'. In essence, the FRE called on judges to evaluate all forms of expert testimony – whether it be specialized, technical, or scientific – when determining admissibility.

One shortcoming of the FRE was that the drafters did not address the *Frye* rule, which led to some confusion among judges in federal courts about whether the *Frye* standard or the FRE should govern the admissibility of expert testimony. This confusion was addressed by the US Supreme Court in 1993, when the Court clarified the standards for the admissibility of scientific evidence in *Daubert v. Merrell Dow Pharmaceuticals* (1993). Jason Daubert, Eric Schuler, and their parents sued Merrell Dow Pharmaceuticals for marketing a drug, Bendectin, given to mothers for morning sickness. The children suffered from serious birth defects and proffered testimony from eight experts to demonstrate the link between the cited birth defects and Bendectin; they presented research of *in vitro* and *in vivo* animal studies, pharmacological studies on the chemical structure of Bendectin showing that Bendectin had a chemical structure that mimicked other drugs known to cause birth defects, and a meta-analysis composed of epidemiological studies that compared the rate of birth defects among children whose mothers had or had not ingested Bendectin during pregnancy. The District Court granted Merrill Dow's motion for summary judgment because the research methodologies cited by the plaintiffs were not generally accepted. The Ninth Circuit Court of Appeals affirmed the District Court's ruling, again on grounds that the research was not generally accepted. Appealing to the US Supreme Court, the plaintiffs argued that the lower courts improperly applied the *Frye* rule when determining admissibility and stated that the FRE should govern the admissibility of expert testimony. The US Supreme Court granted *certiorari*, overturned *Frye's* general acceptance test as the singular rule for granting expert testimony, and stated that the more recently adopted FRE superseded *Frye*.

Daubert also specified that testimony must be both relevant and reliable to be admissible. To assist judges in the evaluation of reliability, the Court provided a list of four nonexhaustive factors that courts could use in their determination of reliability: whether the data can be falsified, whether the data have been subjected to peer review or publication, whether the known or potential error rates are available, and general acceptance of the findings in the relevant scientific community. Federal Rule of Evidence 702 was amended in 2000 to mirror the reliability factors in *Daubert*, stating that expert testimony should be admitted "provided that (1) the testimony is sufficiently based upon reliable facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case" (FRE 702, 2000). In addition to these changes, *Daubert* also placed squarely on the shoulders of the trial judge the responsibility for determining whether scientific evidence is reliable, rather than simply allowing them to evaluate the scientific field's conclusions. Essentially, this decision conveyed that judges are to be evidentiary 'gatekeepers' for scientific testimony. *General Electric Co v. Joiner* (1997) reiterated judges' gatekeeping role and stressed that judges must determine admissibility by evaluating reliability.

Daubert addressed only the admission of scientific testimony but was mute on the requirements for nonscientific

testimony. Therefore, judges could avoid the responsibility of evaluating evidentiary reliability by categorizing an expert's testimony as 'specialized' rather than 'scientific.' In *Kumho Tire Company v. Carmichael* (1999), the Court expanded judges' responsibility to also include evaluating the reliability of nonscientific expert testimony. In this case, the plaintiff was in a serious car crash caused by a tire blowout that resulted in serious injuries and a death. The plaintiff wanted to present testimony from an expert in tire failure analysis to demonstrate that the tire blowout was caused either by a defect in the tire's design or by a manufacturing defect. The trial court excluded the testimony on grounds that the testimony did not meet the standards established in the FRE or the reliability factors specified in *Daubert*. The Supreme Court disagreed with the trial court and instructed judges that their obligation to evaluate testimony goes beyond just the evaluation of scientific knowledge and extends to specialized and technical knowledge as well. Further, they specified that the factors listed in the *Daubert* decision do not apply to the evaluation of nonscientific testimony. In determinations of reliability for specialized and technical knowledge, the Court emphasized that the four factors listed in *Daubert* are not exhaustive, which gave trial judges a wide range of discretion in their determination of reliability. Following the federal courts, many state courts in the United States have adopted admissibility standards based on *Daubert* and its progeny.

Legal Decisions About the Reliability of Expert Evidence

Daubert requires judges to evaluate the reliability of expert testimony, but judges may lack the ability to apply the *Daubert* factors in the absence of scientific training. Studies of judges' abilities to evaluate expert evidence suggest that they have little to no knowledge of social science methods, making it unlikely that they are capable of evaluating empirical methods (Manuto and O'Rourke, 1991). A national survey of state trial court judges found that although 91% of the state judges believed that their role of gatekeeper was appropriate, only 52% felt their education had sufficiently prepared them to perform scientific evidence evaluations (Gatowski et al., 2001). In the survey, judges stated that the four *Daubert* factors would guide their decision to admit or deny expert testimony; however, they lacked the ability to operationalize and understand concepts central to *Daubert*'s criteria for evaluating reliability, such as error rate and falsifiability. When researchers rated the judges' understanding of the four factors, only 6% of judges understood the concept of falsifiability and only 4% understood what is meant by an error rate. Judges demonstrated a better understanding of peer review (71%) and general acceptance (81%).

In one study designed to answer the question of whether judges have the ability to make competent judgments about the reliability and validity of expert evidence, Florida state judges read a summary of an expert's testimony in a hostile work environment case and then ruled on whether they would admit that testimony in court (Kovera and McAuliff, 2000). The judges read proposed expert testimony that either was fundamentally flawed (i.e., was missing a control group, suffered from a confound, or suffered from experimenter bias) or was valid. Judges who had no scientific training admitted the expert evidence equally often regardless of study validity. However, judges with some prior training rated valid research as more legally admissible than invalid science. Judges without scientific training appear to lack the skills necessary to differentiate between valid and flawed scientific testimony and therefore may be ineffective gatekeepers, which could result in the admission of unreliable expert evidence.

Legal Safeguards Against Unreliable Expert Evidence

Although there are a number of procedural safeguards in US courts to protect against jurors basing their decisions on unreliable expert evidence (e.g., cross-examination, judicial instructions, and opposing expert testimony), empirical evidence questions their efficacy. Judicial instructions on the burden of proof likely make jurors more skeptical of all expert testimony and provide no means of better equipping jurors to evaluate the reliability and the validity of the evidence (Kovera et al., 2002). In at least one study, a cross-examination crafted to educate jurors about methodological issues did not improve jurors' sensitivity to variations in the methodological quality of a study on which an expert based her testimony, in comparison to a cross-examination that failed to address methodological issues (Kovera et al., 1999).

Opposing experts demonstrate varying success at educating jurors about scientific validity. Studies show that the presence of opposing experts increases juror skepticism regarding both scientific evidence and the experts who testify (Cutler and Penrod, 1995; Devenport and Cutler, 2004). In one study, opposing experts failed to sensitize jurors to the presence of internal validity flaws in the expert's research, even when their testimony specifically addressed threats to internal validity. Indeed, participants were more likely to convict when a prosecution expert testified, regardless of the scientific validity of the opposing defense expert's study (Levett and Kovera, 2008). However, another study demonstrated that opposing experts might increase both skepticism and sensitivity in a sexual harassment trial (Levett and Kovera, 2009). In a trial simulation, a plaintiff's expert based her testimony on a study that either lacked a control group or was valid. Different versions of the trial also had different types of opposing expert testimony (none, an opposing expert who did not address methodology, or an opposing expert who did address methodology). In the absence of opposing expert testimony, participants rated the defendant to be more liable and the initial expert as more competent and qualified than when an opposing expert also testified. However, when the opposing expert addressed the scientific methodology of the initial expert, jurors rated research that was valid to be more valid than invalid research and jurors rated the expert who presented valid science to be more competent than the expert who presented invalid science. Opposing expert testimony did not affect the main decisions in the case, such as the likelihood that the plaintiff faced a hostile work environment or verdict (Levett and Kovera, 2009). In sum, the available empirical data suggest that opposing experts consistently increase skepticism but either fail to educate jurors about unreliable scientific evidence or fail to influence trial decisions enough to influence key decisions.

Adversarial Allegiance in Expert Testimony

In theory, ethical standards maintain that expert witnesses will be unbiased, impartial, neutral, and objective when testifying in court. Indeed, experts should educate decision makers in a manner that informs and improves decision making. However, adversarial judicial systems may encourage the selection of biased experts. Attorneys are required to seek experts who will represent and support their client's case, which may push attorneys to seek expert witnesses who hold views favorable to their case rather than experts who hold views that are generally accepted within the scientific community. In a survey, judges and attorneys stated that the primary challenge for expert testimony post-*Daubert* is that experts may lose objectivity in a case by becoming advocates for the side that hired them (Krafka et al., 2002). Experts also opine that they feel pressure to provide evidence that supports the position of the party who retained them (Saks, 1990; Saks and Wissler, 1984). Further, it is not unusual for attorneys to push experts into advocacy, encouraging them to provide testimony that is favorable to their case and beyond what the experts' ethical standards should comfortably allow them to say.

This pressure to testify as an advocate may cause experts to overstate conclusions, present information in a biased manner, or present only information that is favorable to the client rather than evidence that is representative of the field's knowledge. Several studies suggest that adversarial allegiance (or allegiance to the side calling the witness) affects fact witnesses. In one study, participants playing the witnesses watched a simulated bar fight and then testified about what they saw one week later. During the intervening week, another participant playing the role of a neutral, court-appointed attorney or an adversarial attorney interviewed the witnesses. The witnesses' testimony was more biased when an adversarial attorney rather than a nonadversarial attorney conducted the intervening interview (Sheppard and Vidmar, 1980).

Despite the expert's ethical obligations to provide impartial testimony, adversarial allegiance appears to affect expert testimony in addition to the testimony of fact witnesses. In one study, graduate students learned that they had been retained by a defense or by a prosecution attorney to interpret an ambiguous criminal case. When the graduate students thought the defense had retained them, they were more likely to reach a conclusion that supported the defendant. When the graduate students thought the prosecution had retained them, they were more likely to reach a conclusion that supported the state. Thus, the retaining side affected their evaluations of case facts (Otto, 1989). In another study, witnesses played the role of either a nonadversarial witness (i.e., one who had been appointed by the court) or an adversarial witness who had been called by either the defense or the plaintiff to testify. Both the judge, who listened to the testimony and who was kept unaware of the study's purpose, and objective raters who listened to tape-recorded versions of the witnesses' testimony found that the testimony from adversarial witnesses was subtly biased toward the side who had called them in relation to the testimony from the neutral witness. Thus, testimony may simply be biased because a particular party called the witness (Vidmar and Laird, 1983). Even in real trials, experts' reports of clinical assessments using instruments with high rates of interrater reliability that are relatively objectively scored show signs of adversarial allegiance. When researchers examined all 23 cases in one state in which opposing experts differed in their assessments of a defendant's psychopathy with a highly reliable scale, experts' reports were more likely to favor the side that hired them (Murrie et al., 2008). Similar evidence of adversarial allegiance was found in a review of clinical psychologists' expert reports in civil sex offender commitment cases (Murrie et al., 2009).

Concurrent Expert Testimony as a Potential Remedy for Adversarial Allegiance

Partisan expert opinions and battling experts in legal settings have encouraged some courts to seek alternative methods of addressing adversarial allegiance among experts. For example, Australian and Canadian courts are modifying the way in which expert testimony is prepared and presented. This technique, referred to as concurrent expert testimony, is designed to reduce adversarial bias and improve the ability of fact finders to understand and evaluate trial evidence (Sanders, 2007). Concurrent expert testimony is a multistep process composed of both a pretrial conference and a two-part joint testimony session (Edmond, 2008, 2009).

The purpose of the pretrial conference is for experts to have an opportunity to indicate areas of agreement and resolve as many differences as possible prior to trial. After the experts have discussed their positions, they produce a joint report that outlines areas of agreement as well as areas of dispute, noting who holds which position (Edmond, 2008, 2009). All participating experts must endorse this report. The absence of the attorneys from the pretrial conference is thought to increase experts' independence from the parties who have retained them and enable the experts to render an impartial opinion (Edmond, 2008).

During the trial proceedings, the experts testify together in a two-part process. In the first phase of testimony, experts have a great deal of testimonial freedom. Each expert outlines his or her personal interpretation of the case along with supporting information. Following this initial presentation, experts are free to ask each other questions and comment on the opposing experts' testimony and evidence. The judge may play an active role in this fact-finding process by asking questions, suggesting additional topics, and directing commentary. Lawyers may also ask questions during this part of the process; however, their manner is less formal than conventional direct examination. The second segment of the concurrent testimony is more typical of adversarial proceedings in which lawyers are free to examine the experts. Lawyers may use this time to cross-examine experts who oppose their position. Cross-examination questions may be presented to one or many of the experts, and experts may also be asked to comment on another expert's answer.

Proponents of concurrent testimony argue that the process enhances neutrality and reduces partisanship on the part of experts because it moves them from close proximity to their lawyers to close proximity to other experts (Edmond, 2008, 2009; Garbis, 2003). Further, concurrent expert testimony is designed to enhance fact finders' comprehension and application of expert evidence to case facts (Downes, 2004; Edmond,

2008, 2009; Garbis, 2003; McClellan, 2007). However, research is needed to determine whether concurrent expert testimony does indeed enhance neutrality among experts, reduce partisanship, and improve fact finders' comprehension of expert evidence and application of it to case facts.

Empirical Research on the Effect of Expert Testimony on Jurors' Decisions

Psychological researchers rely primarily on trial simulation techniques to examine the effects of expert testimony on fact finders' judgments. These trial simulations involve presenting mock jurors (who may be college undergraduates, members of the community, or jurors who have reported to jury duty) with written, audiotaped, or videotaped trial stimuli and measuring behavioral opinions. The trial stimuli vary the presence or absence of expert testimony or some characteristic of the expert testimony.

Empirical Research on Adversarial Expert Testimony

Research on the effects of expert testimony on jury decisions became common in the 1980s. Most of this research has examined whether the testimony of an expert called by one of the parties (an adversarial expert) affected juror or jury decisions. For example, early research examined the question of whether expert testimony influenced juror judgments of guilt. Trial simulation studies demonstrated that when jurors heard expert testimony presented by the defense, they were more likely to return defense verdicts than were jurors who did not hear expert testimony (e.g., Schuller and Cripps, 1998). In contrast, jurors who heard expert testimony presented by the prosecution were more likely to convict the defendant than were jurors who did not hear prosecution expert testimony (e.g., Brekke and Borgida, 1988).

After establishing that expert testimony influenced juror decisions, researchers began to explore whether certain variables moderate the effects of expert testimony on juror judgments. For example, expert testimony has greater influence on jury decisions when it appears early rather than late in the trial (Brekke and Borgida, 1988; Schuller and Cripps, 1998). There is some speculation that early presentation is advantageous because it allows the expert evidence to serve as a framework for understanding other trial evidence. Several studies have also demonstrated that expert testimony is more influential if the expert explicitly links the scientific research to the facts of the case under consideration (Brekke and Borgida, 1988; Schuller, 1992).

Eventually, researchers began to study whether expert testimony improves the quality of juror decisions. Cutler and colleagues (Cutler et al., 1989) presented jurors with a trial simulation in which they manipulated factors affecting the reliability of eyewitness identifications (e.g., the presence of a weapon, disguised perpetrator, or retention interval). They also manipulated the presence of expert testimony describing how these factors influence the accuracy of identifications (e.g., people are less likely to recognize a perpetrator who wore a disguise). In the absence of expert testimony, jurors' decisions were unaffected by factors known to decrease the reliability of eyewitness identifications. After hearing expert testimony on the topic, jurors became sensitive to these factors and used this information in making decisions. Thus, experts may improve fact finders' abilities to make educated decisions. Further, this sensitization effect is more likely to occur when the expert explicitly links the scientific research and the facts of the case (Kovera et al., 1997).

Empirical Research on Nonadversarial Expert Testimony

There may be important differences between the effects of adversarial expert testimony and the testimony provided by a nonadversarial or court-appointed expert. Some have argued that because a nonadversarial expert is proffered by the court rather than one of the parties in a case, jurors may be less likely to critically evaluate the evidence provided by that expert. Indeed, testimony from a court-appointed expert does not have the same sensitizing effect that adversarial expert testimony has on jurors. In one study, nonadversarial expert testimony on the factors influencing the reliability of eyewitness identifications caused jurors to become skeptical of the reliability of all eyewitness identification rather than just those identifications made under unreliable conditions (Cutler et al., 1989). This pattern of effects suggests that jurors are not systematically processing the expert evidence presented by the court-appointed expert, and therefore do not understand the subtleties of that testimony (e.g., that only some eyewitness identifications are unreliable, but not all).

Another concern raised about the use of court-appointed or nonadversarial experts is that their testimony will be prejudicial because jurors may accord it undue weight. Trial simulation research comparing juror evaluations of nonadversarial and adversarial expert testimony demonstrated that jurors find both types of experts equally credible and that their testimony is given similar weight by jurors when making trial judgments (Brekke et al., 1991). Moreover, jurors seem to better remember evidence that is presented by an adversarial expert than evidence presented by a nonadversarial expert, providing additional evidence that jurors do not scrutinize nonadversarial expert testimony as closely as they scrutinize adversarial testimony.

Conclusion

Although expert testimony on many different topics is admitted in court, controversy still surrounds whether judges have the skills and abilities required to evaluate scientific methodology with the goal of preventing junk science from reaching a jury. Because judges receive little education that would enable them to make sophisticated judgments about the reliability and validity of expert evidence, it is important that the judicial system provides scientific training to judges – who are the gatekeepers tasked with keeping poor science out of evidence – and attorneys, who must make arguments before judges to exclude unreliable expert evidence. This sort of training is essential to ensure that these legal actors have the skills necessary to identify bad science. This training is particularly important in light of trial simulation evidence that expert evidence has a great influence on juror decisions, even when it lacks scientific validity, and that the

procedural safeguards in place to help jurors make informed decisions seem ineffective. Additional research is needed to identify other procedures that could help fact finders properly evaluate the quality of expert evidence.

Abstract

Over the past two decades, anthropological research on experts and expertise has flourished. However, rather than treating experts and expertise as new foci of anthropological inquiry, this article explores the historical roots of this field in the anthropology of knowledge, in the postcolonial and reflexive turns of the 1970s and 1980s, and in the rise of science and technology studies as one of the greatest influences on anthropological research in the 1990s and 2000s. The article discusses anthropology's relative disinterest in proposing universal models of experts and expertise and its commitment instead to exploring the processual dimensions of how specialized knowledge and knowers are made, dimensions in which epistemic schemata are formulated, challenged, reproduced, circulated, and, sometimes, institutionalized as 'expertise' by social actors who reciprocally become identified as 'experts' in the process. Yet, the article does show that the anthropological study of experts and expertise extends and refines anthropological reflexivity by encouraging new kinds of interexpert exchanges and relations. In closing, the author predicts that this area of research will continue to be ethnographically and theoretically generative in the future.

Roots in the Anthropology of Knowledge

Experts and expertise are relatively new research subjects for anthropological inquiry; the field has only achieved a distinctive shape and substance since the 1990s. But like so many seemingly novel subjects of research, experts and expertise belong to a broad root system of associated themes with a deep disciplinary history. The anthropology of experts shares common research sites and populations with the anthropology of elites, with the anthropology of science and technology, and with the anthropology of modernity, to name a few of these associations. But what makes it distinctively old and new is its permutation of a long legacy of anthropological research on knowledge and ways of knowing. One is immediately reminded of Malcolm Crick's argument that the anthropology of knowledge "is not a subfield but rather a reminder of what anthropology is centrally concerned with" (1982: p. 287).

Indeed, engagement with certain aspects of knowledge (particularly rationality, logic, and cognition) represented one of the key watersheds in anthropology's disciplinary formation in the late nineteenth and early twentieth centuries. As anthropology began to explore its implications as a rigorous field science (and not solely a laboratory or historical–geographic science) of human culture and society at large, it needed to make sense of the diversity of different kinds of human knowledge it was encountering across the world. As is well known, universal-evolutionary schemas were popular among nineteenth- and early-twentieth century anthropologists as a way of ordering human epistemic diversity and also of elevating Northern/Western/Christian anthropological science above all other forms of human cultural and social knowledge. But, as is also well known, anthropology's integrity as an empirical field science came to militate against universalist paradigms in the twentieth century. The critical debates surrounding characterizations of 'primitive' knowledge in texts like E.B. Tylor's *Primitive Culture*, Sir James Frazer's *The Golden Bough*, and Lucien Lévy-Bruhl's *How Natives Think* are good cases in point. These debates were not only expressions of anthropological science at work, but actually also served to integrate and solidify an anthropological science in the making. They raised questions concerning the universality and relativity of human knowledge that created entire research programs within the fledgling discipline: did so-called primitives have the same logical and cognitive capabilities as 'moderns'? Were their knowledge works different, but equivalently valid, or instead erroneous? How can one comparatively evaluate the epistemic qualities of magic, science, and religion? Lévy-Bruhl argued, for example, that primitives had logical and cognitive capacities like us but that they were unrigorous and unscientific in their application of them. The primitive was thus imagined as antithetical to the modern (scientific) expert. However, Boasians like Paul Radin argued that there were primitive 'men of thought' who were just as rigorous in their application of logic and as creative in their knowledge works as moderns (1927). The advancing critique of universalizing evolutionary paradigms of human cognition and behavior further drew a distinction between anthropology as an empirical science of biological inheritances and effects and anthropology as an empirical science of inquiry into the plurality and unity of human social, cultural, and material forms. In other words, it completed a process that had begun already in the late eighteenth century to distinguish a 'pragmatic anthropology' (in Kant's terms), the study of what human beings make of themselves, from a 'physical anthropology,' the study of what human beings inherit from nature. As the antiuniversalist position became increasingly mainstreamed in anthropology in the twentieth century, the pragmatic study of diverse forms and ways of knowing remained a unifying focus for anthropological inquiry despite its proliferating research sites, topics, and conversations. The key point being that the study of knowledge helped make anthropology what it is today.

Given the long-standing centrality of research on knowledge to the anthropological enterprise, it is unsurprising that the recognition of specialized knowledge as social phenomenon also has a relatively long history in the discipline. Once again, comparative reflection on the status of European science with

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12237-8

other human systems of knowledge was the starting point. But 'experts' and 'expertise' began to appear in the peripheral vision of the field no later than Evans-Pritchard's designation of Nuer chiefs as 'ritual experts' (1940). By the 1960s, references to experts began to appear with more frequency within ethnography, particularly in the tradition of British social anthropology. However, where 'religious experts' and 'ritual experts' (see, e.g., Knutsson, 1963: p. 507) were mentioned, the motivating interest typically remained religion or ritual rather than expertise per se. 'The expert' was a relatively transparent social designation, not one that seemed to admit or reward further anthropological theorization.

In certain respects, this remains the case today (Boyer, 2008). Other fields in the human sciences, notably sociology (e.g., Abbott, 1988; Brint, 1994; Freidson, 2001), behavioral and cognitive psychology (Ericsson and Smith, 1991), and science and technology studies (Collins and Evans, 2002) have expended much more concerted effort on theorization of experts and expertise than anthropology has. There is thus, at least as of yet, no singular anthropological definition of the expert. However, drawing upon the phenomenological, praxiological, and semiological traditions of the discipline, one can at least schematize an expert as an actor who has developed skills in, semiotic-epistemic competence for, and attentional concern with, some sphere of practical activity or 'enactment' (Carr, 2010). By this definition, a car mechanic or a street performer are clearly experts in their respective crafts, although the qualitative dimensions of their expertise are very different (and valued differently) from more widely recognized and institutionally secure experts like doctors, lawyers, or scientists. Indeed, by linking expertise to the combination of skill, competence, attention, and practice, it becomes clear that there is no human being who is not 'expert' in some fashion, much as Gramsci wrote that all men are intellectuals even if not socially validated as such.

Although the very openness of this definition may appear to weaken its analytical capacity, the way it highlights the tension between the experiential-performative and social-institutional poles of skilled knowing and doing actually offers, from the point of view of anthropology, analytical traction in just the right place. What anthropology seeks is a comparative exploration of how specialized knowledge and knowers operate in complex social environments across the world. Among ethnographers working in these fields, there is a common concern with how experts and expertise are made and unmade through social and historical processes. For example, a recent study explores how news journalists are struggling to adapt their traditional expertise and authority as news makers to new scales, temporalities, and institutions of electronic information (Boyer, 2013). A general theory of expertise is not necessary to embark on such projects as anthropologists often find themselves uncompelled by the 'smooth illusion' (Jones, 2010) of universalist models of expertise and more keen to explore the diverse, complicated practices through which epistemic schemata are formulated, performed, authorized, challenged, reproduced, circulated, and, ultimately, institutionalized as 'expertise' by social actors who reciprocally become identified as 'experts' in the process. This deep comparativist attention to the processual dimension of the making of specialized knowledge (and knowledge makers) is what distinguishes the anthropological approach to experts and expertise within the human sciences.

The Mainstreaming of Anthropological Research on Experts and Expertise

One might fairly ask, why has the past two decades seen such rapid growth of anthropological research interest in experts and expertise? The reasons are several. The first factor is undoubtedly anthropology's move to reckon with its colonial legacies in the late 1960s and early 1970s (Hymes, 1969; Asad, 1973) as part of the rise of a broader postcolonial challenge to the legacies of European political, social, and of course also epistemic imposition. Decolonization in the 1950s and 1960s not only fundamentally impacted the rules of the game of anthropological field research and knowledge making across the world, but also challenged the discipline's historical association with the study of 'nonmodern' peoples. Calls increased for symmetrical and critical attention to 'modern' Northern and Western cultures and societies as well. The folkloristic-national and comparative-international wings of anthropological research were to be fused or at least brought into closer alignment. Northern and Western cultures and especially powerful groups in those cultures were no longer to be safely obscured from anthropological illumination. It was, in Laura Nader's famous phrase, time "to study up" (1969).

The validation of new anthropologies of modernity and elites certainly helped to open the gateway for experts and expertise to become legitimate subjects of inquiry. But an even more immediate propellant for an emerging 'anthropology of experts' was the enormous explosion of interest around anthropological science and technology studies in the 1990s and 2000s (e.g., Fischer, 2003; Fortun, 2001; Franklin and Roberts, 2006; Gusterson, 1996; Helmreich, 2000; Knorr Cetina, 1999; Rabinow, 1997; Sunder Rajan, 2006; Traweek, 1988). The circumstances surrounding the rise of science and technology studies to prominence within the human sciences are themselves complex. On the one hand, the inventive hybrid philosophical–empirical programs of figures like Michel Callon, Michel Foucault, and Bruno Latour could certainly be viewed as capable of inspiring cross-disciplinary research programs by themselves. On the other, it seems clear that the so-called postmodern shift to explore the contingencies and limits of scientific/expert knowledge making in the 1970s and 1980s resonated strongly with the crisis of Keynesian technocracy to guarantee an ever-improving modernity as the traditional colonial powers became increasing vulnerable and dependent (e.g., on the oil of an increasingly ungovernable Middle East).

But whatever the deeper cause of its popularity and intuitiveness, what is undeniable is that science and technology studies have massively impacted anthropological research horizons over the past two decades, the concepts and arguments spilling outside of obviously scientific and technical contexts into other domains, particularly into investigations of state making and technocratic contexts as well (e.g., Shore and Wright, 1997; Mitchell, 2002). In the 2010s, there are few domains of anthropological research today that science and technology studies have not touched in some way. At the

same time, it is important to recognize that an expanding 'anthropology of professions' exists that is not simply reducible to the extension of science studies' research into other areas of expertise. Recent ethnographic work on activists (Howe, 2013), advertisers (Mazzarella, 2003), journalists (Boyer, 2005; Hannerz, 2004), lawyers (Mertz, 2007), magicians (Jones, 2010), and politicians (Holmes, 2000), among many other forms of work and life, is exemplary for its plurality of analytical approaches. But it is also characterized by a common, close attention to practices and institutions of expert knowledge. Both the anthropology of professions and anthropological science and technology studies have contributed decisively to the critical mass of ethnographic case material needed for comparative exploration of the singularities and commonalities of expertise across the world. Even in cases where 'expert' and 'expertise' are not the dominant analytic categories, a strong case can be made that this research explores essentially the same dynamics and phenomena, however named. And, increasingly one finds 'expertise' emerging as a dominant analytic for anthropological studies of knowledge (see, e.g., Carr, 2010; Jones, 2010; Roosth, 2013).

The final factor that has helped shape and legitimate anthropological research on experts and expertise has been the methodological reevaluation of disciplinary norms of fieldwork and ethnography, a process that began overtly in the 1980s with the 'reflexive turn' of landmark works like James Clifford and George Marcus's *Writing Culture* but that has recently pursued more systematic methodological reflection on the changing expectations and practices of anthropological knowledge making (see, e.g., Faubion and Marcus, 2009). Although reflexivity is a venerable feature of knowledge in anthropology and human sciences, with better hindsight one can appreciate now that the significance of the reflexive turn was growing recognition that anthropological ethnography needed to be more methodologically self-aware to cope with different expectations for research in a very different world from the imperial era in which it originated. In a word, anthropology, as a matter of survival as a field science, needed to pay better attention to its own 'situatedness.' Although reflexivity is sometimes viewed, particularly by other social sciences, as a sign of empirical weakness or narcissism, anthropology's constant self-analysis of its own limits and patterns of understanding can also be interpreted as making it a more precise and rigorous empirical science. As discussed in the next section, the normalization of anthropological reflexivity over the past three decades has opened up the space for a new theorization of the interexpert relations of fieldwork and postfieldwork knowledge production.

'Paraethnography' and the Relations between Cultures of Expertise

In an important recent article on 'cultures of expertise,' Doug Holmes and George Marcus have noted that anthropological engagements of other experts inevitably bring anthropological knowledge into disquieting but generative juxtaposition with other modes of expert knowledge, some of them distinctively 'paraethnographic' or 'paraanthropological,' which exist outside the networks and institutions of academic anthropology. It is worth citing their evaluation of this situation at length:

> In our experience, ethnographers trained in the tradition of anthropology do not approach the study of formal institutions such as banks, bureaucracies, corporations, and state agencies with much confidence. These are realms in which the traditional informants of ethnography must be rethought as counterparts rather than 'others' – as both subjects and intellectual partners in inquiry. … Here we suggest a particular strategy for re-functioning ethnography around a research relation in which the ethnographer identifies a paraethnographic dimension in such domains of expertise – the de facto and self-conscious critical faculty that operates in any expert domain as a way of dealing with contradiction, exception, facts that are fugitive, and that suggest a social realm not in alignment with the representations generated by the application of the reigning statistical mode of analysis. Making ethnography from the found paraethnographic redefines the status of the subject or informant, asks what different accounts one wants from such key figures in the fieldwork process, and indeed questions what the ethnography of experts means within a broad, multi-sited design of research. (Holmes and Marcus, 2005: pp. 236–237)

It is worth noting that Holmes and Marcus's optimism regarding the prospect of collaboration with other experts in fieldwork is not shared by all anthropologists of experts. Some see instead the threat of an epistemological end point for anthropology in the potential doubling, collapse, and/or cancellation of analytical knowledge forms. For example, if similar social theories are shared by both the analyst and the informant, then what value or expertise is the academic observer really adding to the research process?

While such skepticism provokes interesting reflection, its more dire scenarios of anthropological superfluity remain unrealized. It is never the case, for example, that anthropology fully shares analytical practices let alone professional ideologies with other cultures of expertise. But the situation of contact between anthropologists and other experts can indeed generate friction and misunderstanding. The root of this friction is ultimately sociological and linked to the boundary management of jurisdictions, which Andrew Abbott terms the 'defining relation' in professional life (1988: p. 3). Abbott describes how professions jealously guard the jurisdictions upon which their social privilege depends. When cultures of expertise encounter each other and threaten to overlap, tensions and conflicts inevitably arise. Anthropologists are certainly no strangers to such tensions. Consider, for example, the expanding appropriation of ethnographic research techniques and culture theory in the business world, in government, even in the military. This is expert knowledge that is both ours and not ours, a phenomenon that simultaneously seems to confirm the importance of anthropological expertise and to threaten it. Sigmund Freud describes the anxiety-inducing effect of doubling well: "having been an assurance of immortality … [it] becomes the uncanny harbinger of death." As in all professional life, uncertain jurisdictions undermine identity and authority and often elicit fears of irrelevance or extinction. The concerns that arise from the practice of the anthropology of experts are thus real but could be reframed as follows: On what basis does the representative of one culture of expertise

(the anthropologist) claim legitimate analytical jurisdiction over the members of another culture of expertise and how is this claim enacted? How can an ethnographer document another expert culture without reframing their expert knowledge into the analytical categories of anthropology, thus quietly subverting one's interlocutors to the epistemic norms of the anthropological culture of expertise?

The anthropology of experts can be, in short, unsettling of traditional anthropological research relations. It is often hard to pay proper respect to 'emic' understandings when these represent alternative models of expertise sometimes competing for authority and legitimacy with one's own. Tara Schwegler, for example, found it is dangerously easy to critique the expertise of the neoliberal economists she researched in Mexico (2008), and much more challenging to properly appreciate the integrity and inventiveness of their knowledge making practices. It can also be the case that it is impossible to meaningfully absorb enough of another language and culture of expertise to understand its nuances properly. Truly coming to inhabit another culture of expertise amounts, after all, to a second professionalization process. Finally, even though the anthropology of experts tends to be a fairly cordial and collegial affair, the threats of exclusion and surveillance are never far away. Cultures of expertise are often socially privileged, quasisovereign, and able to restrict fieldwork access, to monitor the acquisition and subsequent circulation of their expert knowledge, and even, if they are so inclined, to police ethnographic and theoretical content. They offer obstacles like intellectual property rights, offices of corporate communications, and nondisclosure agreements, which would-be ethnographers must navigate. And, even in the best access scenarios, the highly specialized task sets, professional credentials, and organizational hierarchies of many cultures of expertise close doors to even the best prepared, most 'insider' ethnographers.

Such unsettling circumstances help explain why anthropological research on experts has spurred serious consideration of the limits and necessary renewal of anthropological knowledge (e.g., Rabinow, 1999), rising even into talk of epistemological dilemmas and crises. But the value of the anthropology of experts in this author's view is precisely that it sharpens and extends our reflexive awareness beyond the glosses of epistemological dilemma and crisis and toward a deeper appreciation of the intersubjective and contextual contingencies of making knowledge. Attention to the dynamics of interexpert exchange in the process of composing anthropological knowledge, for example, makes us more aware of the particularities of anthropology's jurisdiction in the human sciences. We realize how we are experts operating in an ecology of expertise, specialists in field research, in social-theoretical analysis, in ethnographic writing, who coexist and interact constantly with other kinds of skilled knowers and doers. We gain new appreciation of the 'situatedness' both of our knowledge and of others.' We come to understand how some epistemic practices and conditions inhabit many disciplines and jurisdictions and how others are more singular. We are almost by necessity forced to develop forms of reciprocity that balance the interests of analyst and informant in the situation of fieldwork. These are the ethics of what Hannerz has aptly termed studying sideways (2004). Anthropologists of experts have thus done inventive work at creating generative conversations across jurisdictions (e.g., Helmreich, 2009), engaging and translating other expertise to help extend our own into new research areas. In this respect, one feels that the study of experts and expertise is one of anthropology's most successful areas of conceptual and analytical innovation as we have the constant possibility of borrowing and repurposing tokens of expertise drawn from our interlocutors and collaborators.

The anthropology of experts, in sum, enriches and extends the horizon of anthropological reflexivity and anthropological knowledge, not only inviting new modes of interexpert collaboration but also deepening self-knowledge of the distinctive capacities of anthropology's epistemic practices and inspiring new experiments to expand those capacities.

Conclusion

As noted above, more and more anthropologists are becoming interested in research on experts and expertise. New additions to the ethnographic ranks (like Summerson Carr's addiction counselors, Graham Jones's magicians, and Sophia Roosth's molecular gastronomists, to name only a few of many examples) are being incorporated into the broader conversation. And, as anthropological science and technology studies, the anthropology of modernity, and the anthropology of professions explore their overlapping research interests, one finds a shared analytic terminology of 'experts' and 'expertise' becoming more widespread. Thus, it seems very likely that the next decade will see the anthropology of experts and expertise continue to flourish and that part of this flourishing will be more focused conceptual work on operationalizing experts and expertise from an anthropological perspective.

The future, in other words, looks bright. The author highlights one horizon toward which there are hopes the field will grow. Anthropologists still need to push experts outside of their professional comfort zones and to engage their lives more fully. It is still rare to find studies of cultures of expertise that follow experts outside their work spaces, that go home with them, to their children's playgrounds, to family gatherings, to bars and churches, and so on (for a counterexample, see Hugh Gusterson's (1996) resourceful ethnography of nuclear weapons scientists beyond their laboratories). Given the aforementioned difficulties of gaining access to cultures of expertise, it perhaps is not surprising that, once 'inside,' ethnographers have tended to encamp themselves in the relative security of the professional, institutional, and public dimensions of expert lives. Of course, this work has been very rewarding and significant ethnographically. The trouble is that it plays into professional–ideological conceits that what constitutes 'expert' life is fundamentally professional, very often mental, and that all other dimensions of expert lives are trivial, at least when it comes to the constitution of 'expertise.' This is the 'phenomenology of expertise' (Boyer, 2005) in action, how the continuous experience of intense professional and mental activity constitutes a truth horizon in which skilled knowers and skilled knowledge are posited as ontologically supreme. Professional ideologies thus tend to resist (strongly) the idea

that expertise also has roots in informal and situational understandings; that expert rationality possesses a halo of irrational desires, fantasies, and anxieties; that cultural and gender norms help constitute expert subjectivities; and so on. Yet, deeper ethnographic investigation has already shown that the content of expert knowledge is intimately tied to the social and phenomenological experience of the expert knower (Boyer, 2005, 2013). A fuller anthropological portrait of experts and expertise thus demands greater attention to these factors. It is not a question of diminishing anyone's expert authority but rather of subjecting experts to the same standards and practices of analysis anthropology routinely applies to everyone else.

Abstract

Explanation is an important goal of any scientific inquiry. An explanation is a statement or account which makes what is to be explained clearer than it was before and promotes its understanding. There are different kinds of entities to be explained in the social sciences: events or phenomena; scientific laws or theories; the functioning of systems; the meaning of expressions, ideas, or behaviors; actions in the sense of their (moral) justification. The most important kind are events and phenomena. The question 'What is the proper structure and which are the characteristics of a good or adequate explanation of events or phenomena?' is at the heart of a lively debate between the proponents and opponents of different models of scientific explanation. The best known ones are the deductive-nomological model of scientific explanation and the statistical-relevance model of probabilistic explanation. These models presuppose a comprehensive and well articulated knowledge base which is not available in most of the social sciences. More realistic recent alternatives are the model of aleatory explanation and, as the most promising one, the embedding theory of scientific explanation which will presumably play a leading role in future discussions of the issue.

Explanation is an important goal of any scientific inquiry. Many social scientists would say that it is the most important one. Nevertheless, the expression 'explanation' as it is used within the social sciences is still a vague and ambigous term with at least five different connotations: (E1) the explanation of an event or a phenomenon, (E2) the explanation of a scientific law or theory, (E3) the explanation of the functioning of a system, (E4) the explanation of the meaning of an entity (e.g., an expression, an idea, a behavior), and (E5) the explanation of an action in the sense of its (moral) justification. In each case, an explanation is a statement or account which makes what is to be explained clearer than it was before and promotes its understanding. But how this is to be achieved for the different variants of the concept of explanation and what are the characteristics of a good or adequate explanation in each case is a controversial topic not only in the social sciences but in science in general (cf Stegmüller, 1983). The focus of discussion has been, from the beginning, on the first variant E1, i.e., the explanation of events or phenomena. This variant and the problems involved will be the main subject of this article.

Explanation-Seeking Questions

Explanations can be understood as answers to certain questions, the so-called *explanation seeking questions*. In the social sciences, a very important type of explanation seeking questions refers to actions of a certain kind performed by a certain person. An explanation of individual actions is not only of interest in itself, but it is also required for a proper understanding of many *macrosocial* phenomena that are construed as the aggregate result of individual actions of large numbers of persons. As Little (1991) puts it, all social processes, causal influences, systemic interactions, etc., are ultimately embodied in the actions of individual actors within a specific social and natural environment. This may be one reason why most publications about explanation in the social sciences primarily, or even exclusively, deal with the explanation of human actions.

Suppose a person p performed an action of kind a. There are at least the following eight questions relevant to the explanation of this singular action a of person p (cf Tuomela, 1977):

(Q1) Why did p do a?
(Q2) What was the reason of p for doing a?
(Q3) What was the motive (emotion, feeling, sensation, personality characteristic) which led p to do a?
(Q4) Which of the wants (desires, decisions, duties, obligations, norms) of p brought about his or her doing a?
(Q5) Which of the beliefs (thoughts, considerations, knowledge) of p brought about his or her doing a?
(Q6) What was the purpose (intention, aim, end, goal) of p for doing a?
(Q7) How is it possible that p did a?
(Q8) What does p's doing a mean (express)?

Answers to these questions are not independent from each other. Q1 could be answered by referring to causes and reasons for action a, whereas Q2 seems to accept only the latter. Q4 and Q5 which already mention certain kinds of reasons in the formulation of the question are included in Q2. Thus, an answer to Q4 and Q5 can be transformed into an answer to Q2. An answer to Q3 can be interpreted as an answer to Q1 or Q2. Tuomela assumes that answers to questions Q1–Q5 are statable as:

(A1) p did a because of c.

Here c gives the causes or reasons for p's doing a. All answers to Q6 can be paraphrased in the form

(A2) p did a in order to do g.

Here g is p's goal action for the purpose of which a was performed. An illustration of A2 would be: p saved money in order to enjoy life after retirement.

Tuomela claims that answers of the type A2 can be further reduced to answers of the type A1 and that the expression 'because of' in A1 signifies a causal relation between a and c. Answers to *how possible questions* of type Q7 are incomplete variants of A1. Explanations of individual actions by means of

sociological variables such as minority status, social class, or social position of an agent are good examples of answers to questions of type Q7.

Answers to questions of type Q8 are of a totally different nature. They belong to category E4, i.e., the explanation of the meaning of an entity, in that they reveal an additional understanding of action *a*. The so-called *speech acts*, that are linguistic actions, may illustrate this type: if action *a* of person *p* consists of the utterance 'I will do that!,' an appropriate answer to the question 'What does *p*'s saying "I will do that!" express?' might be 'This utterance of *p* is a promise, not only an announcement or a prediction.'

Answers of type A1 seem to be fundamental in the explanation of human actions. Differentiating between types of psychological explanations allows a more comprehensive treatment of component *c* of A1.

Types of Psychological Explanations

Bunge and Ardila (1987) suggest the following classification of psychological explanations: (T1) tautological explanations, (T2) teleological explanations, (T3) mentalist explanations, (T4) metaphorical explanations, (T5) genetic explanations, (T6) developmental explanations, (T7) environmental explanations, (T8) evolutionary explanations, (T9) physiological explanations, and (T10) mixed explanations. Each type shall be briefly explained (in the sense of E4) and illustrated by two simple examples.

T1: *Tautological explanations* refer to basic capabilities or mental faculties: person *p* is able to anticipate (or anticipates) events because of *p*'s forethought capability. Person *p* is able to think about (or thinks about) herself because of *p*'s self-reflective capability.

T2: *Teleological explanations* refer to goals or purposes (cf component *g* in A2): person *p* sold his shares in order to maximize his profit. Person *p* studied medicine in order to become a doctor.

T3: *Mentalist explanations* refer to mental events: person *p* developed a neurosis because *p* suffered from an intrapsychic conflict. Person *p* works so hard because *p* is highly motivated.

T4: *Metaphorical explanations* refer to analogies with physical or social processes or with animals or machines: person *p* processes information like a parallel processing computer does. Person *p*'s drivings follow the same principles as a steam boiler.

T5: *Genetic explanations* refer to the genetic endowment of a person: person *p* has a high intelligence because her or his parents also had a high intelligence. Person *p* suffers from Alzheimer's disease because *p* carries two apolipoproteine E type 4 alleles.

T6: *Developmental explanations* refer to stages or levels of biological or psychological development or to events in the persons's past: person *p* does not understand the lever laws because *p* is not yet in the stage of formal operations. Person *p* suffers from agoraphobia because *p* has experienced a severe trauma in early childhood.

T7: *Environmental explanations* refer to external conditions and factors: person *p* shows a high response rate because *p* is working under a variable ratio reinforcement schedule. The agoraphobic symptoms of *p* are weakened because *p* is massively exposed to the threatening stimuli.

T8: *Evolutionary explanations* refer to the survival value of a behavior or behavior tendency, its selective advantages or disadvantages: male persons show sexual jealousy in order to ensure paternity in putative offspring by preventing encroachment by competing males, and this behavior tendency has evolved because of the selective advantage of a greater reproduction rate of these persons (cf Buss, 1997). Persons have a high pain threshold under duress because of its survival value.

T9: *Physiological explanations* refer to physiological, especially neurophysiological and endocrinological, processes and mechanisms: introverts are more arousable than extraverts because introverts have a lower threshold for activation in the ascending reticular activating system than extraverts. The depressive person *p* experienced an elevation of her or his mood because *p* took a cyclic antidepressant which increased the chemical neurotransmitter serotonin.

T10: *Mixed explanations* are combinations of two or more of the above mentioned types of explanation. Mostly, explanations are not pure cases of one type, but combinations of at least two types, i.e., they are mixed explanations. Cases of one type usually provide only a partial answer to the respective explanation seeking question. In answers of the type A1 to explanation seeking questions and in most of the given examples of the different types of psychological explanations, the relation term 'because' occurs. It links that which is to be explained to that which explains. A characterization of this relation is provided by the so-called *models of explanation*.

Models of Explanation

Explanation is one of the main subjects of the philosophy of science. So far, many different models of explanation have been constructed, most of them incompatible with one another (cf Salmon, 1989). Each model attempts to answer at least two questions: (1) What is (the structure of) an explanation? and (2) What is a good (proper, appropriate, adequate) explanation? Some answers to these questions will be briefly outlined.

The Deductive-Nomological Model of Explanation

According to this classical view, an explanation is an *argument* which shows that the phenomenon to be explained can be inferred from certain other facts by means of specified general laws. This type of argument may be schematized as a deductive inference of the following form (cf Hempel, 1965):

(D-NE)	$L_1, L_2, \ldots, L_r$	General laws
	$C_1, C_2, \ldots, C_K$	Statement of antecedent conditions
	E	Description of the empirical phenomenon to be explained

E as the description of the phenomenon to be explained is called the *explanandum* (*sentence*). The statements of antecedent conditions, which make assertions about particular facts, and the general laws together form the *explanans*, i.e., that which explains. Explanations of this kind are called explanations by deductive subsumption under general laws, or *deductive-nomological explanations*. (The root of the term 'nomological' is the Greek word 'nomos' for law.)

D-NE gives an answer to the question 'What is (the structure of) an explanation?' A comparison between this structure and the one underlying the examples of the different types of psychological explanations reveals that most of the latter are stated in an elliptical form, viz., '*E* because of *c*' (cf A1). The component *c* refers only to a subset of the antecedent conditions $C_1, C_2, \ldots, C_k$ that are required for a proper explanation of the explanandum *E*, and the general laws, if there are any at all, are totally omitted. Thus, explanations of the form '*E* because of *c*' do not count as proper explanations.

To give an answer to the second question, i.e., 'What is a good explanation?,' requires the formulation of *conditions of adequacy*. In the case of the model of deductive-nomological explanation, there are four such conditions (cf Hempel, 1965):

(R1) The explanandum must be a logical consequence of the explanans, i.e., the explanandum must be logically deducible from the information contained in the explanans.
(R2) The explanans must contain general assumptions or hypotheses, and these must actually be required for the derivation of the explanandum.
(R3) The explanans must have empirical content, i.e., it must be capable, at least in principle, of test by experiment or observation.
(R4) The sentences constituting the explanans must be well confirmed.

It is not easy to find examples of deductive-nomological explanations in the social and behavioral sciences that display the proper structure and satisfy the conditions R1–R4. One example may be: the phenomenon to be explained is Peter's frequent aggressive behavior in the presence of his mother. The explanation is given with reference to the theory of operant behavior. The explanandum statement *E* can be formulated as 'Peter shows a high frequency of aggressive behavior if his mother is present.' The principle of positive reinforcement 'If a positive reinforcer is presented contingent on the occurence of a behavior, then the frequency of this behavior will increase' can be the law statement *L*. At least two statements of antecedent conditions are required, viz., A_1 'Contingent on Peter's aggressive behavior, his mother regularly shows attentive behavior,' and A_2 'His mother's attentive behavior is a positive reinforcer for Peter.'

In this case, the explanandum *E* seems to be deducible from the explanans, i.e., the conjunction of *L*, A_1, and A_2. Thus, R1 as the first condition of adequacy seems to be satisfied. But what about the conditions R2–R4? That depends on the status of *L*. If *L* would have empirical content and could be regarded as well confirmed, R2–R4 would be satisfied too. With regard to *L*, two problems arise: (1) According to its critics, *L* is no empirical law, but only a logical consequence of the definition of the concept of a positive reinforcer (the much discussed problem of circularity of the empirical 'law of effect'); (2) even if this were not the case, *L* is not a well confirmed universal law because its validity depends upon conditions which are not explicitly mentioned in *L*. One important condition is the following: (C1) there exists no other behavior in the respective situation contingent on the occurrence of which a more effective positive reinforcer is presented. If there exists only one such other behavior in the case of Peter and his mother – and this is not excluded by the antecedent conditions A_1 and A_2 – a quite different law statement would become relevant, viz., the 'law' of parallel reinforcement. If there exist even two or more of the behaviors excluded by C1 which seems to be the usual case in unrestricted natural environments, it is difficult to find an appropriate law statement at all.

This example is representative of the problems that conflict with any attempt to apply the model of deductive-nomological explanation to the social sciences. Universal deterministic laws as they are required by the model are hard to find in this domain. Nevertheless, Hempel (1965) who is the best known proponent of the model defended its significance for the social sciences and even for history. He considered any deviation from the standards set by the model as leading to insufficient and incomplete explanations. Nowadays, few social scientists are willing to share his view. But the idea of a *nomological* social science with strict laws and explanations of the deductive-nomological type is still alive (cf McIntyre, 1996).

The trust in the possibility of a change in the direction of a nomological social science is based on a certain feature of scientific explanations, viz., that any explanation of an event is an explanation of that event *under a certain description*. The explanandum statement *E* in a deductive-nomological explanation does not represent the event to be explained as such, but the event under a certain description. It might be that the current situation in the social sciences is the consequence of an unfavorable choice of modes of description – that, at least, is the argument. Other choices which would lead to a redescription of the subject matter of the social sciences could, perhaps, reopen the way to a truly nomological social science. Unfortunately, McIntyre (1996) who is a confirmed supporter of this view has not produced any laws, offered any new social theories, or even given any redescriptions so far.

The Statistical-Relevance Model of Probabilistic Explanation

It may be difficult to find genuine nomological laws in the social sciences, but it is easy to find statements which describe *statistical regularities* between events. '85 percent of the persons who have a panic disorder and who undergo an exposure therapy experience relief from their symptoms' is an example. Concrete percentages or probabilities do not occur in every statistical statement. Instead, fuzzy terms like 'nearly all,' 'most,' 'the majority,' 'more than half,' etc., are used. Hempel (1965) had recognized this situation very early and broadened the scope of his theory of explanation by proposing his much discussed *model of inductive-statistical explanation*.

Referring to the above example of a statistical law, an explanandum *E* could be 'Person *p* experiences relief from his or her symptoms of panic.' Appropriate antecent conditions would be A_1 'Person *p* has a panic disorder' and A_2 'Person *p* undergoes an exposure therapy.' The statistical law in conjunction with these two antecedent conditions constitutes

the explanans in this case. The inductive-statistical explanation of *E* could be expressed in two ways: (1) the inductive probability of the explanandum given the explanans amounts to 0.85. (2) The explanans inductively supports the explanandum in the degree 0.85 (cf Schurz, 1995/96).

The objections against Hempel's model of inductive-statistical explanation led Salmon (cf 1989) to the formulation of his *statistical-relevance model of probabilistic explanation*. Whereas in Hempel's model an explanation of an event is an inductive argument that confers upon the event to be explained a high inductive probability, an explanation of an event according to Salmon's model is an assemblage of factors that are statistically relevant to the occurrence of the event to be explained, accompanied by an associated probability distribution.

Salmon and Salmon (1979) gave the following example to clarify this notion: Albert, an American teenager, is convicted of stealing a car. A sociologist who attempts to explain that act of delinquency will presumably look for certain factors that are known to be relevant to delinquent behavior, e.g., sex, age, marital status of parents, religious background, socioeconomic status, residence (rural/urban/suburban), etc. Each of those factors, as well as many others, is assumed to be statistically relevant to delinquency in the sense that the probability of delinquency is different for boys than for girls, different for urban dwellers than for rural youngsters, different for children whose parents have remained married than for those from broken homes, etc. If any of these factors does not make some difference in the probability of delinquency, it will be discarded as irrelevant, and hence as lacking in explanatory value.

To explain Albert's delinquent behavior, the population of American teenagers to which Albert belongs is partitioned into a series of subclasses in terms of such relevant factors as those already mentioned. For each subclass in the resulting partition, the probability for delinquent behavior on the part of members of that subclass will be determined. Then, Albert will be assigned to one such subclass in terms of his actual attributes, e.g., 17-year-old male, suburban dweller, middle-class undivorced parents, etc., and the probability will be cited for that subclass. If the number of relevant factors which enter into the partition is large, the probability obtained in a given case may be quite low. For Salmon, that is not crucial. What matters is that the relevant factors be taken into account in partitioning, and that the probabilities associated with the various subclasses be accurate.

This model is confronted with two problems. (1) The requirement of a homogeneous relevant partition of the reference class (in the example: the population of American teenagers) is not easy to meet. In most cases in which explanations of single events are looked for in the social sciences, a comparable probability distribution will not be available. (2) The fact that an event counts as appropriately explained even if the probability value associated with the respective subclass of the partition may be very low comes into conflict with deeply rooted preconceptions about proper explanations. With regard to Tuomela's explanation seeking questions, the best that could be achieved by this kind of explanatory efforts is an answer to a question of type Q7, i.e., an answer to a how possible question.

These problems of the statistical-relevance model of explanation led others to challenge its claim to be a model for the explanation of single events. Schurz (1995/96) comes to the conclusion that the genuine explananda of statistical laws are not single events but sample frequencies. In his discussion of the explanatory value of causal modeling techniques in the social sciences, Woodward (1989) assumes that the statistical information in the delinquency example may contribute to the explanation of facts about population level parameters but not to the explanation of why any particular boy became a delinquent.

Even if this critique of Salmon's model were to be accepted, it would still be of value to the social sciences, since it provides a standard for a deeper statistical-causal understanding of social phenomena as, for example, juvenile delinquency, unemployment, or terrorism in certain reference classes. This standard could also be applied to the increasing use of meta-analytic methods for explanatory purposes in the social sciences when several explanatory variables are involved at the same time (cf Cook et al., 1994).

The Model of Aleatory Explanations

A more recent model of causal explanations of specific events is the model of aleatory explanation (see **Table 1**) introduced by Humphreys (cf 1989). He agrees with Salmon that causal explanations are possible within the realm of chancy, or aleatory, phenomena. But in his model, in contrast to Salmon's, no probability value is assigned to an explanation. The demands on the knowledge base are much lower than in Salmon's model, e.g., no complex probability distribution on the basis of a homogeneous relevant partition of a reference class has to be available.

What is required for a proper explanation of a specific event Y in S at t are two lists of causes of Y, i.e., a list of *contributing* and a list of *counteracting causes*. In Humphreys' model, for something to be a cause it must invariantly produce its effect. But causes in this model are probabilistic causes, and they produce changes in the value of the *chance* of the effect. A contributing cause of Y produces an increase, a counteracting cause of Y a decrease in the value of the chance of Y.

This model seems to be applicable in various contexts within the social sciences (cf Henderson, 1993). It takes account of the fact that social phenomena are usually the result of multiple causal influences. It does not presuppose the existence of complete lists of all influences which, positively or negatively, affect a given outcome. Aleatory explanations are conjunctive. They can be improved by including additional probabilistic causes which may come up in further research.

Table 1 The canonical form for casual explanations of specific events (cf Humphreys 1989, pp. 286 f.)

Request for the explanation:
What is the explanation of Y in S at t?
Appropriate explanation:
Y in S at t [occurs, was present] because of Φ despite Ψ
Notes
'Y' is a term referring to a property or change in property.
'S' is a term referring to a system.
't' is a term referring to a time.
'Φ' is a (non empty) list of terms referring to contributing causes of Y.
'Ψ' is a (possibly empty) list of terms referring to counteracting causes of Y.

The model has already been applied to explanations within a theory of social interaction in small groups (cf Westmeyer, 1996). But its importance goes well beyond that particular context. Take, for example, the interactionistic theory-frame of Magnusson (1980) under which many theories of social interaction can be subsumed. One fundamental assumption of this theory is that changes in the probabilities for behaviors of a person in a certain situation are a function of changes in the factors within this situation. Such determining within-situation factors are the physical situation, behaviors of the person concerned, and behaviors of the interaction partners.

In terms of Humphreys' model, 'Y' would refer to a change in the probability of a behavior of the person concerned; 'S' would refer to the setting in which the intrasituational dynamic interaction between the person and the interaction partners takes place; 't' would refer to a certain point or period in time at which the change in the probability of the behavior occurs; 'Φ' would refer to the set of all those determining within-situation factors, the changes of which facilitate (contribute to) the occurrence of Y; and 'Ψ' would refer to the set of all those determining within-situation factors, the changes of which inhibit (act counter to) the occurrence of Y. Contributing and counteracting causes could be identified by methods of event sequence or time series analysis.

The Embedding Theory of Explanation

Most of the models and notions of explanation dealt with so far are strongly connected to the so-called *statement view* of scientific theories that assumes theories to be sets of laws or theoretical assumptions. A very different picture is given by the *structuralist view* which is a variant of the model-theoretic approach to the understanding of scientific theories. Here, theories are reconstructed as complex set-theoretical structures. The structuralist program has already demonstrated its fruitfulness in the analysis of various theories from the social sciences (cf Stegmüller et al., 1982; Westmeyer, 1992).

From this point of view, explaining a phenomenon means to explain it *within the context of a certain theory*. This requires to show (1) that the phenomenon can be construed as an element of the set of intended applications of the theory, and (2) that the theory can be successfully applied to that element. In short, what has to be done is to embed the phenomenon into the theory. This leads Bartelborth (1996) who gives the most detailed account of this idea to speak of the *embedding theory of explanation*. For a concrete example of this type of explanation in the social sciences see Westmeyer (1996). He shows that it is possible to combine the embedding of a phenomenon into a certain theory with the application of Humphreys' model of aleatory explanation.

The embedding theory is the most promising variant of the *unification approach* (cf Kitcher, 1989) to the problem of explanation. 'Explaining as unifying' is a notion which increasingly attracts the attention of philosophers of science. It paves the way for an integrative treatment of explanation and understanding (cf Schurz and Lambert, 1994) which is especially of interest to those social scientists who are used to construe explaining and understanding as basically different scientific activities. It is in accordance with a coherence theory of truth and fully compatible with basic epistemological tenets of the more recent constructionist and constructivist approaches to the social sciences. These characteristic features of the embedding theory give rise to the expectation that this theory will play a leading role in future discussions of the issue of explanation in the social sciences.

Abstract

Explanations or attributions of somatic feelings or events have mostly been investigated in reference to mental disorders such as panic disorder and hypochondriasis. These cognitions have salient effects on the diagnosis, management, and course of disorders according to various evidence-based psychological models. Each person experiences the events that happen to him/her and attempts to understand them. Explanatory style refers to the way individuals understand for themselves why an event, positive or negative, has happened. This understanding has many facets and the way people perceive an external event (or a bodily sensation) is influencing their reaction to it and consequently has an effect on them. Explanatory style is considered a psychological attribute and is a term used alternatively to attribution style. This sometimes causes confusion. Explanatory style, as defined, can influence diagnosis and treatment as well as illness behavior.

Explanatory Style and Treatment

Whereas attribution theories have their roots in social psychology – and go back to the seminal work of Fritz Heider (2013), early twentieth century – various models have been developed in the context of clinical psychology with a view to investigating the processes by which individuals attempt to explain the causes of behavior and events. Explanatory style has mostly been investigated in the context of certain mental disorders e.g., depression, phobias, panic disorder, hypochondriasis, and other somatic symptom disorders. In hypochondriasis, the belief that one suffers from a serious medical problem largely develops from the fact that patients misinterpret physical sensations, as symptoms of a serious disease. These perceptions lead to help-seeking behaviors, which typically aim to receive a diagnosis and potentially result in appropriate or inappropriate medical reassurance, information about the diagnosis, treatment, or further referral for specialist assessment and/or more medical tests. If the problem is not resolved, despite its short-term benefits in reduction of illness worry, diagnosis or reassurance acts as a maintaining factor for anxiety, allowing for the development of new seeking behaviors (Salkovskis, 1991, 1996) – which may in turn result in increased levels of medical consultations and investigations (Conroy et al., 1999). Kirmayer and Taillefer (1997) also suggest that attribution of physical sensations to physical causes results in help seeking. Interestingly, they argue misattribution alone is crucial toward the development of somatic symptom disorders as it deprives one of turning to oneself in order to seek alternative explanations and develop coping behaviors.

The explanatory style of an individual influences his/her adherence to treatment (Long et al., 2007). It has been shown in clinical practice that patients' compliance to the prescribed treatment (be it pharmaceutical or other health advice) is crucial in order to ensure recovery. Nonadherence incurs clinical failures and consequently financial burdens, not only for the individual but also for the health system and society as a whole. Clinicians attempting to reduce noncompliance have developed general and specific interventions. 'Compliance therapies' have been trialed by clinicians, based on cognitive behavioral techniques. Trained clinicians deliver specific therapeutic interventions that emphasize medication cessation and relapse, normalizing rationales for stigma and recognition of characteristic prodromal symptoms (Rief and Rojas, 2007). One of the most frequently used approaches involves meetings with the doctor, aiming to increase positive attitudes toward treatment, recognition of side effects and reporting them. It is widely acknowledged that among the most important parameters in achieving compliance is the doctor–patient relationship, i.e., the therapeutic alliance. In this respect, it has been shown that standard encounters with the physician (the psychiatrist in this particular research) involving nonspecific counseling, thereby stimulating positive attitudes toward treatment, can be as effective as more specific interventions for noncompliance in the long term (Jackson and Kroenke, 2008). Undisputedly, compliance is more difficult to achieve in the treatment of chronic (long term) disorders (Zolnierek and DiMatteo, 2009).

Explanatory Style: Cognitive Processes and Behavior

When someone suffers from an illness, the symptoms of the illness can influence his or her behavior. Additionally individuals suffering from a somatic illness are ascribed the role of 'the ill person,' which implies relief from certain everyday chores (absence from work support from their social milieu). Barsky and colleagues (Barsky and Wyshak, 1990; Barsky, 1992) ascribed a central role to cognitive processes including the process of perceiving somatic sensations as signs of a disease. They postulated that illness anxiety increases as a result of a vicious cycle of misattribution, selective attention to physical symptoms and 'amplification' of interoception. This amplification of interoceptive awareness, i.e., of perception of somatic sensations and/or of the physiological condition of the body (Craig, 2002) eventually leads to the intensification of physical symptoms. It is also worth noting that illness worry or health anxiety, which is now considered a dimensional

construct (Longley et al., 2010), has been linked to catastrophizing, avoidance, body vigilance, and attribution (explanation) (Rief and Broadbent, 2007; Henningsen et al., 2011).

Illness anxiety and illness behavior are studied extensively in the context of medically unexplained symptoms (MUS) and Somatic Symptom and Related Disorders. Several studies on illness perception have shown that patients' beliefs about the cause of their illness (i.e., somatic, psychological, normalizing/environmental explanations) play an important role in pathogenesis and maintenance of MUS and Somatic Symptom and Related Disorders such as Somatic Symptom Disorder, Illness Anxiety Disorder, and Conversion Disorder (Voigt et al., 2010). A number of these studies have reported that patients with MUS/somatic symptom disorders tend toward an organic causal illness perception style (MacLeod et al., 1998; Nimnuan et al., 2001; Rief et al., 2004; Henningsen et al., 2005; Douzenis and Seretis, 2013). However, many patients report multiple symptom attributions – including psychological and social – and employ complex explanatory resources to account for their symptoms (Rief and Broadbent, 2007; Douzenis and Seretis, 2013). Finally, research on the role of memory is bound to have important implications in the field of explanation of illnesses and illness behavior: memory influences top–down psychological processes in the symptom perception of patients with MUS (e.g., Houtveen and Oei, 2007; McFarlane et al., 2008; Bogaerts et al., 2010) and is also involved in doctor–patient encounters (Rief and Broadbent, 2007).

Exploratory Data Analysis: Univariate Methods

David C Hoaglin, Sudbury, MA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The exploratory approach, developed by John W. Tukey, focuses on steps that precede any formal inferences. At its core lie four main themes: display (usually graphical), reexpression (via a mathematical transformation), resistance (to unusual behavior in data), and residuals (from subtracting a summary or fitted model). The most familiar exploratory data analysis techniques include the stem-and-leaf display, the boxplot, and median polish. The article discusses themes and techniques and illustrates their application to data in four examples.

Since about 1970, the phrase 'exploratory data analysis' (EDA) has referred to the approach and techniques promoted by John W. Tukey and various collaborators. EDA emphasizes relatively simple numerical and graphical techniques for looking at a set of data, to see what 'appearances' are present, and removing 'partial descriptions' of those appearances, in order to look further. These steps are intended to precede any attempt at drawing inferences from the data, a process that Tukey labeled 'confirmatory data analysis.' Statisticians have used exploratory techniques since they began to work with data, but extensive developments in statistical inference (roughly during the first half of the twentieth century) had relegated exploration to a secondary role as 'descriptive statistics.' Tukey sought to restore the balance between exploratory and confirmatory data analysis. In the process, mainly in his book *Exploratory Data Analysis* (1970–71, 1977), he introduced a variety of new techniques. Within a few years basic EDA techniques, especially displays, were available in statistical software. By the end of the century, a number of those techniques had become part of statistical instruction at all levels, including elementary school.

Main Themes of EDA

At the core of the EDA approach lie four main themes: display, reexpression, resistance, and residuals.

1. Displays (most of them graphical) allow the analyst to see the behavior of the data and, as analysis proceeds, the behavior of residuals and various diagnostic measures. EDA emphasizes the frequent use of displays, to ensure that unexpected features are not overlooked. The most common displays include the stem-and-leaf display, the boxplot, scatterplots of residuals, and the spread-versus-level plot.
2. Reexpression involves applying a single mathematical transformation (such as the square root or the logarithm) to each data value. The aim is to simplify, and thus make more effective, the analysis of the data. Depending on the structure of the data, the simplification may come from promoting symmetry, constancy of variability, straightness of relationship, or additivity of effect. EDA asks, at nearly the first opportunity, whether the scale in which the data are presented is satisfactory. If not, it freely tries a likely transformation.

   The reexpressions most often used in EDA come from the family of functions known as power transformations, which take y into y^p (almost always with a simple value of p such as 1/2, −1, or 2), together with the logarithm (which, for data analysis purposes, fits into the power family at $p = 0$). For example, in a study of the levels of nicotine in the blood and urine of smokers and nonsmokers (Russell and Feyerabend, 1975), the analysis gained simplicity by reexpressing the nicotine concentrations in the logarithmic scale.
3. Resistance provides insensitivity to misbehavior or unusual behavior in data. An analysis or summary is resistant if an arbitrary change in any small part of the data produces only a small change in the analysis or summary. EDA emphasizes resistance because experience suggests that 'good' data seldom contain less than about 5% gross errors.

   The notion of robustness is akin to resistance, but not the same. Robustness generally implies insensitivity to departures from assumptions surrounding an underlying probabilistic model. (Resistance is one aspect of 'qualitative robustness.')

   In summarizing the location of a sample, the median is highly resistant. (In terms of efficiency, it is not so highly robust because other estimators achieve greater efficiency across a broader range of distributions.) By contrast, the mean is highly nonresistant. A number of exploratory techniques for more structured forms of data, such as the 3-group resistant line for (x,y) data and median polish for two-way layouts, provide resistance because they are based on the median.
4. Residuals are what remain of data after a summary or fitted model has been subtracted out, according to the schematic equation

$$\text{residual} = \text{data} - \text{fit}$$

   For example, if the data are the pairs (x_i, y_i) and the fit is the line $\widehat{y}_i = a + bx_i$, then the residuals are $r_i = y_i - \widehat{y}_i$.

   EDA regards a careful examination of the residuals as an essential step in analyzing a set of data. This emphasis gains from the tendency of resistant analyses to provide a clear separation between dominant behavior and unusual behavior in the data. When the bulk of the data follows a consistent pattern, that pattern determines a resistant fit. The residuals then contain any drastic departures from the pattern, as well as the customary chance fluctuations.

Unusual residuals suggest a need to check on the circumstances surrounding those observations. As in more traditional practice, the residuals can warn of systematic difficulties with the data – curvature, nonadditivity, and nonconstancy of variability.

The examples and discussion that follow illustrate displays (via stem-and-leaf displays and boxplots), resistance (median polish), residuals, and reexpression.

Example 1: Florida Voting (Stem-and-Leaf Displays)

The initial results of the US presidential election in 2000 focused intense attention on the state of Florida, where the difference in total votes cast for George W. Bush and Albert Gore was so small that state law required a recount and thus delayed the outcome. Among the unusual features of the Florida voting was the relatively large number of votes cast in Palm Beach County for Patrick Buchanan, the candidate of the Reform Party (3407 out of 430 762 votes). Critics argued that most of those votes had been intended for Gore, but were recorded for Buchanan because of a problem with the type of ballot.

A number of analyses compared the results in Palm Beach County against those in other counties. Without explaining the reasons for those choices, one analyst selected the data from the 30 counties in which Bush received more than 30 000 votes and calculated the ratio of the number of Buchanan votes to the number of Bush votes, concluding that the probability of the ratio in Palm Beach County by pure chance was extremely small.

For those 30 counties Figure 1 shows a stem-and-leaf display of the percentage of votes for Buchanan (out of the total number of votes for four candidates: Bush, Gore, Buchanan, and Ralph Nader). In overall outline this display resembles a histogram with an interval width of 0.1%, but it shows more detail of the data values by using the 0.01% digit of each percentage instead of merely enclosing a uniform amount of area. This feature makes it easy to go back from a part of the display to the individual data values (and their identities) in the listing of the data – a valuable step in EDA.

Several alternatives and refinements permit the stem-and-leaf display to accommodate a wide variety of data patterns. The interval width (that is, the range of data values represented by one line in the display) may be 2, 5, or 10 times a power of 10; and stray observations may be listed separately at each end so as not to distort the scale. The use of positive and negative stems readily handles sets of residuals.

6|2               Santa Rosa
7|9               Palm Beach
```

Figure 1 Stem-and-leaf display of the percentage of votes cast for Patrick Buchanan in the 30 Florida counties in which George W. Bush received more than 30 000 votes. The unit for the leaves is 0.01%.

In Figure 1 Palm Beach County's 0.79% for Buchanan is noticeably high (indeed, another EDA technique would flag it as 'outside' and hence deserving investigation). But the 0.55% for Marion County and the 0.62% for Santa Rosa County are also noticeable at the high end. The layout of the stem-and-leaf display makes it easy to include tags that identify a few data values at either end.

The analyst's choice of counties with more than 30 000 votes for Bush naturally raises a question about the extent of support for Buchanan in the other 37 counties of Florida. Figure 2 shows a stem-and-leaf display for all 67 counties. In the context of the whole state, Palm Beach County no longer stands out; seven counties had a percentage for Buchanan higher than 0.79%, and two of those were above 1.6%. Those seven counties, however, are small; most cast fewer than 8000 total votes for the four candidates. Also, geographically, they are all located in north Florida, far from Palm Beach County. Thus, among counties with larger numbers of voters, it still appears that Palm Beach County produced an unusually large percentage for Buchanan. A stem-and-leaf display of the vote totals (not shown) reveals a clear gap around 40 000. Modifying Figure 1 to include all counties with totals greater than 40 000 would add three counties, whose percentages for Buchanan were 0.21%, 0.26%, and 0.47%.

Even after this modification the position of Palm Beach County in Figure 1 does not form the basis for a conclusion. It does invite further examination. Other analysts responded, taking into account the voting in counties throughout the United States, precinct level voting in Palm Beach County, and voting in other Florida elections. For example, even if one uses only data from Florida counties, a scatterplot of the percentage for Buchanan against the percentage of Bush (or against the percentage of Gore) shows that Palm Beach County is very far from the other counties.

Example 2: Teen Drivers (Stem-and-Leaf Display, Boxplots)

In the United States drivers under 20 years of age are involved in fatal motor vehicle crashes at a much higher rate than older drivers. An analysis of data for 2003 calculated the rate of fatal crashes (per 100 000 licensed drivers of 16–19 years of age) for each state and the District of Columbia (O'Donnell, 2005). The stem-and-leaf display in Figure 3 shows large differences among states (New Hampshire was lowest at 29, and North Carolina was highest at 105), and labeling other low rates and high rates suggests a geographic pattern.

The broad grouping of the four census regions (Northeast, 9 states; Midwest, 12 states; South, 16 states plus DC; and West, 13 states) provides the basis for the parallel boxplots in Figure 4. In a boxplot (also called a 'schematic plot') the box extends from the lower hinge (an approximate quartile) to the upper hinge and has a line across it at the median. The 'whiskers' above and below the box show the extent of the data, except for observations that are likely strays (defined according to a rule based on the hinges). Such strays (when present) appear individually, in order to focus attention on them. The general intent is to indicate the median, outline the middle half of the data, and show the range, with more detail at the ends if needed.

One message of Figure 4 is that the typical (median) rates of fatal crashes were lowest in the Northeast and highest in the South with the Midwest and the West roughly halfway between. The vertical extent of the boxes shows greater variation in the Northeast and the South, but the Midwest and the West each have one stray. In the Northeast the short whiskers (relative to the extent of the box) and the low position of the median in the box suggest displaying the regions' data in detail.

The plot in Figure 5 uses the states' two-letter abbreviations as the plotting symbols. In the Northeast Rhode Island, Pennsylvania, and Maine had substantially higher rates than the other states. In the Midwest the stray is Missouri. In the South the highest rate (105 in North Carolina) was nearly twice the lowest (55 in Maryland), with no sizable gaps in between. And in the West, Utah was noticeably low, and Nevada, Arizona, and Montana were noticeably high. With such an initial exploration as background, an analysis might consider such factors as restrictive licenses for teen drivers (especially 16-year-olds), use of safety belts, enforcement of speed limits and alcohol laws, and characteristics of roads.

Figure 4 Parallel boxplots of the rates of fatal crashes by census region.

Example 3: Hotel Occupancy (Median Polish, Residuals)

In 1983, as several new hotels were under construction in Boston, operators of existing major hotels were concerned about the impact on their business. Table 1 shows the occupancy rates for 11 major Metropolitan Boston hotels, month by month, for January through June 1983. One approach to exploring such a two-way table uses an additive fit of the form

Figure 5 Plot of the rates of fatal crashes for all states by census region.

Table 1 Occupancy rates of major Metropolitan Boston hotels, 1983 (%)

Hotel	*January*	*February*	*March*	*April*	*May*	*June*
Bostonian	56	65	71	86	87	93
Colonnade	30	24	34	73	74	80
Copley Plaza	52	62	80	84	83	84
Hyatt	52	71	72	89	86	90
Lenox	38	45	55	71	78	78
Marriott Long Wharf	77	84	86	95	94	96
Meridien	54	63	61	73	81	82
Park Plaza	40	42	47	64	72	72
Parker House	57	60	60	78	82	85
Ritz-Carlton	45	53	52	75	83	82
Sheraton Boston	49	37	60	78	85	82

$$\widehat{y}_{ij} = m + a_i + b_j$$

with a row effect, a_i, for each hotel and a column effect, b_j, for each month. The EDA technique known as median polish arrives at such a fit by iteratively subtracting row medians and column medians, first from the table of data and then from the table left by the previous iteration. The common value, m, is determined by centering the effects so that the median of the a_i is 0 and the median of the b_j is 0. The use of the median gives the fit resistance: isolated behavior of the data in a few cells of the table will tend to have only a minor impact on the fit.

For the hotel occupancy rates **Table 2** shows the two-way table of residuals, $y_{ij} - \widehat{y}_{ij}$, bordered by the hotel effects, the month effects, and the common value. The month effects (ranging from −22.0 to +15.0) show occupancy rates in Boston hotels increasing substantially from January to June. Among the hotel effects the Marriott Long Wharf (at 21.5) stands out as having higher occupancy than the other hotels, and the Colonnade and the Park Plaza (at −12.0 and −12.5, respectively) were substantially lower. A stem-and-leaf display of the residuals (not shown) calls attention to three sizable negative residuals (−20.0, −19.0, and −15.0) and one sizable positive residual (+13.5). These indicate that the Colonnade (beyond its generally low occupancy) had unusually low occupancy in February and March, that the Sheraton Boston had unusually low occupancy in February, and that the Copley Plaza had unusually high occupancy in March.

Example 4: Everyday Reexpressions

In a number of applications from a variety of fields, a reexpression has become so customary that no one mentions it. By the time the data or results are presented, they are already in the transformed scale. Examples include established relationships in science and engineering, as well as contemporary data (see also Hoaglin, 1988).

For earthquakes the Richter scale expresses the strength in logarithmic units (base 10). The magnitude is defined as the logarithm of the amplitude recorded by a particular type of seismograph (at a specified distance from the epicenter).

In measuring the intensity of sounds, the decibel scale is logarithmically related to sound pressure.

Measurements of the fuel consumption of automobiles often involve determining the number of gallons of gasoline that a car used on a standard test course. Thus, the ratings in miles per gallon are the result of a reciprocal transformation.

Literature

The first published presentation of EDA was the preliminary edition (1970–71) of the book by John W. Tukey, whose 1977 edition represents the definitive account of the subject. Mosteller and Tukey (1977) also include substantial discussion of exploratory attitudes and techniques. Tukey's (1962) paper on the future of data analysis set the stage.

The two volumes of the *Statistician's Guide to Exploratory Data Analysis* (Hoaglin et al., 1983, 1985) discuss the rationale and development of a number of EDA techniques, explain and illustrate connections with classical statistical theory, and introduce new techniques.

Hoaglin et al. (1991) extend the basic attitudes and techniques of EDA to factorial analysis of variance.

Broader discussions of the roles of exploratory and confirmatory data analysis in scientific inquiry appear in Tukey (1972, 1980).

Table 2 Result of applying median polish to the hotel occupancy rates: table of residuals, bordered by effects and common value

Hotel	*January*	*February*	*March*	*April*	*May*	*June*	*Hotel effect*

Exposure Therapies and Stress Inoculation: A Brief Overview

David Phillips and Dean Lauterbach, Eastern Michigan University, Ypsilanti, MI, USA

Abstract

Exposure therapies represent the most empirically supported treatments for anxiety and related disorders. Furthermore, stress inoculation training (SIT) uses exposure techniques to inoculate at-risk populations from anticipated stress. Unique iterations of exposure exist for each disorder, population, and patient, yet foundational elements span diagnostic categories. In the broadest sense, exposure therapies are a group of treatments that use the presentation of feared stimuli as a therapeutic tool. This article addresses the theoretical models, the common elements of practice, limitations, and future directions of exposure therapy.

Theoretical Models of Exposure Therapy

A variety of theoretical models attempt to explain the etiology of pathology and the efficacy of exposure therapies. Both cognitive and neurological explanations have been well articulated, but behavioral conditioning, operant and classical, is exposure's cornerstone. As such, the following section details the two most influential conditioning models: Mowrer's two-stage theory and the emotional processing model (EPM).

Mowrer's Two-Stage Theory

Mowrer's (1960) two-stage theory for the acquisition and maintenance of fear incorporates both classical and operant principles. The first stage of Mowrer's model suggests that neutral stimuli become feared stimuli when paired with already feared unconditional stimuli. The 'Little Albert' experiment (Watson and Rayner, 1920) is a classic example of this process. In a laboratory setting, 'Albert,' an infant, is presented with a white rat, which initially provokes no fear (the neutral stimulus). Fear of the rat (the conditioned stimulus) quickly develops when Watson and Rayner (1920) begin pairing the presentation of the rat with an alarming sound (i.e., the unconditioned stimulus). Mowrer argues that this process is adaptive when it allows organisms to generalize conditioning to situations that should be avoided, but this process becomes dysfunctional when the organism overgeneralizes to safe situations.

Across anxiety-related disorders, conditioned stimuli elicit distressing emotional responses that the organism actively avoids/seeks to escape (Richard et al., 2007). Therefore, avoidance behavior comes under operant control; the second stage of Mowrer's theory (1960). A common example is avoiding all forms of transportation following a traumatizing car accident. Automotive transportation (the conditioned stimulus) is avoided because it is associated with the fear of the collision (the unconditioned stimulus). Avoiding all forms of transportation mitigates anxiety, which is reinforcing in the moment but dysfunctional in the long term.

Although Mowrer's theory does not address how exposure works (Richard et al., 2007), the two-stage theory implies behavioral interventions that alter operant contingencies and the valence of conditioned stimuli (Forsyth et al., 2007); two key components to exposure therapies. This being said, the two-factor theory is not the primary basis of any modern exposure therapy. Critics of Mowrer's theory point to instances where individuals acquire fear responses but do not engage in avoidance behavior, or exhibit avoidance behavior despite reporting the absence of subjective distress (Richard et al., 2007). Also, many individuals diagnosed with anxiety or related disorders cannot recall a learning event that accounts for the first stage (i.e., the classical conditioning stage). Lastly, some argue that the two-stage theory does not adequately account for the complexities of nonphobic fears that often have intrapersonal and social consequences (Richard et al., 2007). Despite these shortcomings, Mowrer's theory serves as an elegant exemplar of how etiology and maintenance can have different mechanisms of causality.

Emotional Processing Model

Foa and Kozak's (1986) EPM posits that anxiety and related disorders develop from escape and avoidance behavior under stimulus control of a latent fear network (Rauch et al., 2012; Cahill et al., 2009; Foa and Kozak, 1986). This fear network contains all information, responses, and meaning related to the feared stimuli, and it is differentiated from other information structures by its reactivity and negative valence. For example, someone with agoraphobia might have a fear network that codes crowded places, elevators, and bridges as triggers for avoidance and escape. The fear network is adaptive in that it helps protect the individual from encountering stressful stimuli, but the pervasive overgeneralization to nondangerous situations hampers vocational, social, and health needs.

EPM suggests that activation of the fear network via exposure and subsequent habituation are essential therapy components. Activation and habituation are thought to decrease sensitivity to feared stimuli and mediate cognitive restructuring (Foa and Kozak, 1986). Some EPM therapies use explicit cognitive procedures to alter the fear network once activated (Resick and Schnicke, 1992), while others assert that only exposure is necessary to foster cognitive change (Foa and Kozak, 1986). EPM differs from Mowrer's theory in that it does not require single trial learning to account for the development and expansion of a fear network. Furthermore, EPM posits a latent cognitive construct to account for stimulus generalization and operant relationships. As such, EPM is a blend of cognitive and behavioral explanatory features.

Overall, EPM has considerable explanatory value, but current research on active mechanisms has challenged EMP's emphasis on habituation. Specifically, research suggests that new learning (i.e., inhibitory learning) is more predictive of treatment outcome than habituation. In fact, mandating in-session habituation may hinder the amount of new learning that can take place during a given session (Craske et al., 2008). Other critics challenge EPM's narrow etiological view, suggesting that interpersonal factors, such as low self-efficacy, maintain distress (Mineka and Thomas, 1999). Despite these criticisms, the EPM remains the most researched and widely applied theoretical model to date.

Treatment Characteristics of Exposure Therapy

Exposure therapies have been historically associated with treatment of syndromes previously classified as anxiety disorders in the Diagnostic and Statistical Manual of Mental Disorders, 4th edition, text revision (DSM-IV-TR; American Psychiatric Association, APA, 2000). Specifically, post-traumatic stress disorder (PTSD), obsessive-compulsive disorder (OCD), social phobia, specific phobia, panic disorder, and agoraphobia have responded well to exposure treatment. The DSM-5 (5th edition, APA, 2013) has moved PTSD into the new 'trauma- and stressor-related disorders' category and OCD into the new 'obsessive-compulsive and related disorders' category. According to this new codification, exposure's purview extends beyond anxiety disorders, but the specific disorders have not changed.

Unique iterations of exposure exist for each disorder (Richard and Lauterbach, 2007), but certain general procedures typify all applications. Specifically, each manualized treatment consists of exposure, generalization, and response prevention efforts. This section describes these general characteristics.

Exposure

Exposure procedures can be divided into *in vivo* exposure, imaginal exposure, and *in virtuo* (i.e., virtual reality) exposure. *In vivo* exposure occurs when an individual physically confronts a feared stimulus in its natural environment or artificially in session (Lauterbach and Reiland, 2007). For example, an individual with a phobia of flying might sit in a taxied plane as a preliminary form of *in vivo* exposure. To fully activate the fear network, *in vivo* exposures should mimic (or actually be) the feared stimuli (Craske and Barlow, 2008).

Imaginal exposure refers to the detailed recollection of feared stimuli (Cahill et al., 2009). During imaginal exposure individuals narrate their trauma in the present tense, even when narrating a past event, to increase intensity and emersion (Zayfert and Becker, 2007). For example, a person recounting a physical assault during imaginal exposure would be encouraged to say "I can see someone moving from my periphery" versus "I saw someone move from my periphery." Treatments often blend both *in vivo* and imaginal methods, presenting the chosen stimuli for prolonged periods and in multiple settings (Zayfert and Becker, 2007).

Advancements in technology have created a third exposure class known as *in virtuo* exposure, which utilizes virtual reality (VR) simulations to foster a therapeutic anxiety reaction (Bouchard et al., 2007). *In virtuo* exposure typically consists of head-mounted displays with motion trackers (Bouchard et al., 2007). Merits of *in virtuo* exposure include increased treatment control (Goncalves et al., 2012), higher acceptability (Garcia-Palacios et al., 2001), and a higher range of plausible exposure scenarios than *in vivo* (Bouchard et al., 2007). For example, in the treatment of combat PTSD, *in virtuo* exposure offers the ability to generate an interactive environment that mimics the patient's deployment setting. Thus far, *in virtuo* exposure has been successfully incorporated into treatments for phobias (Bouchard et al., 2007), PTSD (Rothbaum et al., 2001), panic disorder with agoraphobia (Pérez-Ara et al., 2010), and OCD (Kim et al., 2009). In short, VR holds the potential of revolutionizing exposure therapy.

In-vivo, imaginal, and *in virtuo* exposures share a common implementation protocol. At the outset of therapy, exposure events are chosen collaboratively by the therapist and client, and usually placed in a rank ordered anxiety hierarchy (Cahill et al., 2009). Treatment consists of progressing through this list, beginning with the least distressing and working toward the most distressing. Movement through the hierarchy is traditionally dictated by habituation, as measured via subjective units of distress (Richard et al., 2007).

Generalization

Generalization, in the context of therapy, refers to meaningful declines in anxiety, fear, and avoidance that persist across settings and locations (Sturmey et al., 2007). In exposure therapy, generalization of new learning into real world settings is the ultimate goal of therapy (Craske et al., 2008), and fostering generalization takes careful planning (Sturmey et al., 2007). In terms of the EPM, generalization requires activating the fear network's underlying structure (Foa and Kozak, 1986). As such, exposures should incorporate the most evocative components of the encoded fear (both physical and personal response aspects; Lang, 1977). For example, imaginal exposure of a motor vehicle accident should include detailed descriptions of the vehicle and logistics of the crash, as well as the smells, sounds, and physiological responses associated with the fear network.

The theme of generalization was embedded throughout the previous section on exposure. For example, the exposure hierarchy is an explicit method of ensuring that powerful and diverse exposure experiences occur. Failure to access essential aspects of the fear network can severely limit generalization (Foa and Kozak, 1986). As a simple example, consider a patient with a phobia of dogs. Exposure to a Yorkshire Terrier may work well for eliminating the fear response to small dogs, but might presumably do little for large breeds. To facilitate generalization across all breeds (i.e., settings), exposure should include a variety of dogs, with special attention to the most feared type. While varying exposure is a crucial element, generalization is also affected by the presence of avoidance behaviors during session. The following section describes this issue.

Response Prevention

Response prevention refers to the cessation of the avoidance behavior that has been maintaining the fear response

(Abramowitz et al., 2013). Exposure should always be paired with some form of response prevention to maximize treatment engagement and to put avoidance behavior on extinction (Abramowitz et al., 2013). For example, doing an exposure treatment for a germ phobia would require contact with a feared 'contaminated' surface (e.g., a restroom door handle), as well as the prevention of immediate hand washing, which is a form of escape. Failure to prevent the escape response impedes exposure and treatment outcome (Abramowitz, 1996). Response prevention also pertains to the thoughts and internal processes that maintain avoidance behavior such as recitation of songs or prayers, or conjuring distracting mental images (Purdon, 2004). For example, an individual suffering from repugnant sexual obsessions may recite a spiritual text to 'purify' his mind. Continuing this response during imaginal exposure blocks new learning/habituation, defusing exposure's therapeutic power. Response prevention also entails the careful management of fast acting anxiolytic medications, like Alprazolam, that function as avoidance behaviors and hamper exposure (Deacon, 2007).

A topic related to response prevention is safety signals, which are stimuli that diminish the negative valence of feared stimuli (Lohr et al., 2007). Learning that takes place in the presence of safety signals does not generalize to settings where safety signals are not present (Craske et al., 2008). Craske and Barlow (2008) note that people, food, money (e.g., to make emergency calls), medications, and familiar landmarks are potential safety signals that, like avoidance responses, disengage the individual from exposure, thus blocking the therapeutic effects (Craske et al., 2008). As such, detection and elimination of safety signals is integral to successful exposure treatment.

Stress Inoculation Training: Exposure as Prevention

Exposure procedures have also been incorporated into a preventative treatment for high-risk populations. Stress inoculation training (SIT) is a multifaceted cognitive behavioral intervention for stress and was developed in the 1980s. SIT is similar to the aforementioned exposure therapies in that it uses imaginal and *in vivo* exposure to build coping skills and increase functionality. Yet, SIT operates under a unique conceptual model and typically employs exposure as a preventative, rather than curative, procedure. SIT has been applied to multiple nonclinical (Saunders et al., 1996) and select clinical populations (Cahill et al., 2009) with varying degrees of success. Overall, SIT has proven to be an efficacious therapy that has amassed a considerable amount of research (Meichenbaum, 1985; Meichenbaum and Deffenbacher, 1988; Spencer, 2010). The following sections will detail SIT's conceptual model, procedure, and applications.

Conceptual Model of SIT

SIT's underlying framework is a transactional model of stress (Meichenbaum, 1985). According to SIT, stress emerges from a dynamic interplay of the individual, the environment, and emotional/physiological reflexes (Folkman, 1984). Just as outside forces introduce potentially stressful material, individuals engender stress via their interpersonal relationships and coping style (Meichenbaum, 1985). For example, an individual who responds to high job-place stress by drinking heavily during the week experiences stress as a result of both external (work demands) and personal (excessive drinking) factors. SIT places special attention on the role of cognitions, a mediator of the environment-behavior stress transaction (Meichenbaum, 1985).

Cognitions, in the context of SIT, can be understood as an appraisal of one's environment and self-efficacy (Folkman, 1984). Cognitions do not introduce new material, rather they make sense of the environment in a manner that produces or inhibits stress. Hopko and Hughes (2005) conceptualize this in terms of the well-known behavioral three-term contingency (A-B-C), suggesting that cognitions (B) evoke stress reactions (C), rather than the events themselves (A). As an example, imagine a single mother who works by day, goes to night school, and comes home to care for her son. According to SIT, the extent to which this situation (A) is internalized as stressful (C) depends on how the mother appraises her situation (B) and her ability to cope. It is easily seen that holding the belief "This is impossible; I am a failure" results in more stress than "Although this is hard, I am building a stable life that I can be proud of."

Implementation of Intervention

SIT is focused on changing distorted cognitive structures using a variety of methods. These cognitive structures, also known as schema, refer to underlying beliefs, assumptions, and perspectives about the world and one's self. Similar to typical exposure therapies, SIT relies on imaginal and *in vivo* exposure to alter cognitions. SIT also places a strong emphasis on cognitive restructuring and personalized treatment formulation (Meichenbaum, 1985). SIT organizes these techniques into three treatment phases: conceptualization, skills acquisition/rehearsal, and application (Meichenbaum, 1977). The following paragraphs detail the three phases of SIT, with special attention to exposure components.

The 'conceptualization phase' involves assessment of the client's problems, symptoms, and expectations, training in relaxation skills, and education about the nature of stress and the utility of previously used coping strategies (Meichenbaum and Deffenbacher, 1988). Imagery-based recall of recent stressful events, an exposure technique, is often used to identify the patient's stress patterns. Behavioral assessments, similar to *in vivo* exposure, are also used to test the environment and demonstrate how the client's typical behavior generates stress (Meichenbaum, 1985). This procedure encourages a proactive approach toward resolving stressors, which essentially inoculates against stress (Meichenbaum, 1996). For example, learning how to talk about work performance with one's boss prior to a crisis should alleviate stress in the event of a crisis. The information gathered from these procedures is aggregated and synthesized into a personalized clinical 'reconceptualization' of the client's stress. This revamped model emphasizes the transactional nature of stress and coping, the patients' control, and pinpoints symptoms for intervention.

'Skills acquisition/rehearsal' is the second phase, and dismantling studies suggest it is indispensible (Horan et al., 1977; Vallis, 1984). This phase of SIT focuses on building the client's skill-set to facilitate effective, resilient coping. Client input guides this phase, and the SIT therapist manual notes that: "the training approach adopted by SIT is to offer the variety of coping techniques in a cafeteria style, whereby clients can experiment in determining what works best for them" (Meichenbaum, 1985: p. 54). The skills acquired during this phase can be separated into problem- and emotion-focused coping.

Problem-focused coping attempts to address stress by directly altering environmental variables. These types of coping strategies are only appropriate in situations where environmental control is actually possible. In contrast, emotion-focused coping directly addresses the subjective meaning of the situation, and is often used in situations where environmental variables are beyond control (e.g., chronic pain or grieving loss). It is often the case that situations warrant both problem- and emotion-focused coping methods. The most typical SIT skills include cognitive skills, relaxation training, and self-instructional training.

SIT's third and final phase is 'application.' This phase is concerned with the generalization of the skills acquired during the acquisition phase via incremental induction (or inoculation) of stressful stimuli (Meichenbaum and Deffenbacher, 1988). Consistent with the flexible approach of the prior phases, the application and follow-through phase can entail a wide range of procedures to meet the needs of the specific individual. Techniques include imagery rehearsal (past and future events), behavioral rehearsal, and *in vivo* practice. The central theme of this phase is that generalization should not be left to chance. During therapy, the individual should come into contact with a wide variety of stressors to ensure mastery and application of SIT skills in daily life. SIT frames success as continued application of skills, not an elimination of experiences that could produce stress (Meichenbaum, 1985).

Nonclinical and Clinical Applications of SIT

The bulk of SIT research focuses on nonclinical populations in high stress environments. SIT has been effective for coping with stress-inducing environments involving anger, medical illness, surgery, performance evaluation, and vocational stress such as combat, police work, and teaching (see Meichenbaum, 1985 for a comprehensive review). SIT's research footprint has shrunk over the past decade, but dissertations continue to explore SIT's effectiveness. Most recently, SIT has been successfully applied to single mothers attending college (Spencer, 2010), members of a residential training center (Mayer, 2008), and college students (Ayers, 2010). These studies consistently find that SIT is effective for managing stress in nonclinical populations.

SIT has also been applied to traumatized populations (Cahill et al., 2009). Kilpatrick et al. (1982) created a manualized version of SIT to treat rape survivors. SIT has produced results equivalent to prolonged exposure (PE) for the treatment of rape victims, but follow-up analysis favored PE (Foa et al., 1991, 1999). SIT's utility in treating other PTSD populations has been mixed. For example, SIT has demonstrated limited efficacy in treating combat PTSD populations (Hensel-Dittmann et al., 2011). Yet, it is difficult to assess the efficacy of SIT for PTSD, because SIT is typically a control condition. In such studies, researchers restrict the use of exposure to make a clear distinction between SIT and the primary exposure intervention of interest (Foa et al., 1999, 1991). SIT is an intentionally dynamic intervention and these studies adulterate SIT's theoretical/treatment model and their conclusions should be analyzed with caution.

Obstacles to Implementing Exposure Therapies

The title of Richard and Gloster's (2007) chapter adeptly identifies the obstacles hindering exposure therapy's utilization: *Exposure Therapy Has a Public Relations Problem: A Dearth of Litigation Amid a Wealth of Concern*. Indeed, exposure therapy is suffering from a pervasive skepticism that has severely hampered its adoption in the clinical arena. A study of primary care patients with PTSD found that only 16% reported receiving exposure therapy (Rodriguez et al., 2003). VA rates are similar with less than 20% of PTSD specialists reporting consistent use of exposure techniques (Rosen et al., 2004). This problem is not limited to PTSD. Freihei et al. (2004) site that only 38 and 31% of surveyed therapists reported frequently using exposure for OCD and social anxiety disorder, respectively; furthermore, 79% reported rarely or never using exposure for panic disorder.

The poor utilization of exposure therapies is curious when considering the potential cost savings and efficacy of the various treatments. For example, a microsimulation of the financial impact of successfully treating Operation Iraqi Freedom veterans with PTSD found a projected savings of 165 million dollars over the course of 2 years, if all treatment-seeking veterans received empirically based exposure therapies (Kilmer et al., 2011). The American Psychological Association, the International Society of Traumatic Stress Studies, and the Department of Defense have fully endorsed exposure therapies as 'gold standard' treatments. Yet, the empirical literature reveals skepticism going back to early applications of exposure for PTSD (Hembree and Cahill, 2007). Select PTSD researchers have suggested that high levels of exposure are aversive and potentially retraumatizing (Pitman et al., 1991, 1996; Tarrier et al., 1999), whereas others have challenged these conclusions on the grounds of limited empirical support, lack of systematic research, and inadequate controls (see Hembree and Cahill, 2007, for a thorough review).

Nonetheless, those critical of exposure have made a lasting impact on the field. Becker et al. (2004) found that 59% of nonspecialized therapists and 48% of trauma-specific therapists report believing exposure increases a patient's desire to drop out. Furthermore, 87% of the main sample and 55% of specialists expressed the belief that exposure likely increases arousal. Consequently, exposure has accrued an almost medieval reputation, which one author likened to 'A Clockwork Orange' style behavioral modification (Prochaska and Norcross, 1999). Exposure's press in the public sector has also suffered. Slater (2003) quotes one journalist as stating that exposure is "torture, plain, and simple" (as cited in Richard and Gloster, 2007).

One reservation regarding exposure treatments is that patients will discontinue treatment prematurely. Hembree et al. (2003) analyzed 25 randomized controlled trails and found that attrition in exposure treatment (20.5%) did not statistically differ from cognitive therapy (22.1%) or EMDR (18.9%). Similarly, a meta-analysis of psychotherapy for PTSD (Bradley et al., 2005) found no significant differences in completion rate across different treatment types, and Imel et al. (2013) found that higher exposure does not result in higher attrition.

Furthermore, multiple studies have found a weak connection between exposure therapy and symptom exacerbation. In the most thorough analysis to date, Foa et al. (2002) reported that a minority of participants exhibited symptom worsening during treatment, and that such worsening was associated with the initiation of imaginal exposure. Importantly, those who showed symptom worsening during treatment were not more likely to drop out of treatment and did not have different treatment outcomes. As such, the evidence suggests that exposure may cause symptom exacerbation in a small percentage of patients, but this does not influence drop out or treatment outcomes (Hembree and Cahill, 2007).

The resistance to utilizing exposure, despite ample evidence dispelling skepticism, indicates that a major dissemination problem exists. Becker et al. (2004) report that only 13% of their sample attested to formal imaginal exposure training for PTSD and 47% reported limited or no familiarity. As such, serious attention should be given to generating and evaluating methods of dissemination (Gunter and Whittal, 2010).

Future Directions

Exposure and Pharmacotherapy

Pharmacotherapies such as selective serotonin reuptake inhibitors have demonstrated short-term effects comparable to exposure therapies (Deacon, 2007). Yet, research does not support the assertion that combined treatment is typically better than exposure alone (cf Marks et al., 1993). Furthermore, the paucity of research on combined treatment for PTSD, social phobia, GAD, and specific phobias preclude any definitive conclusions (Deacon, 2007). Multiple explanations have been offered to account for the weak findings. As previously stated, medications, especially benzodiazepines, are thought to inhibit exposure and operate as a form of medical escape. Relatedly, limited research suggests that learning during exposure with medications may not generalize to medication free settings (Deacon, 2007).

Fortunately, a new vein of pharmacotherapy has demonstrated promising preliminary findings. D-cycloserine (DCS), a partial *N*-methyl-D-aspartate (NMDA) agonist, in combination with exposure has produced impressive results (Ressler et al., 2007). DCS has been found to enhance cognitive learning in spatial memory tasks by acting on NMDA receptors, which are thought to mediate extinction and associative fear conditioning (Ressler et al., 2007). Studies of PTSD (de Kleine et al., 2014), specific phobia (Norberg et al., 2008; Ressler et al., 2007), OCD (Kushner et al., 2007), and generalized social anxiety disorder (Smits et al., 2013) have produced convincing results, suggesting that learning potentiators can dramatically enhance the effects of exposure therapy. Furthermore, DCS has been shown to accelerate remission (Ressler et al., 2007), decrease dropout (Kushner et al., 2007), and work with pediatric populations (Mataix-Cols et al., 2014). More research is needed to fully investigate this promising application of pharmacology and exposure.

Conclusion

Exposure therapies comprise the most efficacious treatments for anxiety and related disorders, as well as nonclinical stress. Exposure is a versatile technique that has been repackaged into numerous behavioral and cognitive treatments. Current theory suggests that exposure's utility stems from its ability to activate and foster amelioration of the latent fear network, thought to mediate distress. Traditional approaches have used a habituation model to describe exposure's affect on the fear network, but current research suggests that new learning (e.g., inhibitory learning) accounts for the therapeutic benefits of exposure. Regardless, exposure procedures that incorporate multiple modes of exposure, prevent avoidance responses, and program for generalizability engender positive outcomes. Unfortunately, dissemination of exposure into the clinical realm has been challenging, due to fears that exposure harms or unduly distresses patients. More research, training, and empirical approaches to dissemination are needed to rectify exposure treatment's perception in the public and clinical spheres. Nonetheless, exposure's future is promising with new pharmaceutical applications and innovative protocols for complex populations on the horizon.

Extended Schools

Alan Dyson, University of Manchester, Manchester, England

Abstract

Schools in many countries are developing extended roles. These take them beyond their core academic concerns and involve them more widely in the lives of their students and in families and communities. There are many approaches to developing these extended roles, but they can be seen as lying on a continuum from a focus on remedying deficits to a focus on developing assets. The evidence for the effectiveness of these approaches has limitations but is nonetheless promising. Ultimately, the development of extended roles raises fundamental questions about the role of schools and the purposes of education.

The core task of schools everywhere is to develop the cognitive capacities of their students and, particularly, to enable them to make progress through some more-or-less well-defined academic curriculum. However, in many places the role of schools is being extended beyond this core task. Schools are engaging with other, nonacademic aspects of their students' lives – with their social development, for instance, or their health and well-being. In order to do this, they are developing close partnerships with other, noneducational services, such as social care, youth work, or health. Often, they seek to work more closely with families, involving them in their children's education, helping them develop more effective parenting skills, and perhaps finding ways to support them through difficulties. They may also see themselves as having a role in the wider communities they serve, offering adult education provision, opening their facilities to community use, or contributing to community development and area regeneration.

In some cases, developments of this kind originate in the values and enthusiasms of particular school principals and their staff. In other cases, there are more formal local or national initiatives which support and encourage schools to move in this direction. In the USA, for instance, there have been a series of initiatives to develop what are variously known as 'full service' or 'community' schools (see, for instance, Dryfoos, 1994, 2005; Blank et al., 2003). In the Netherlands and Belgium, there are 'brede scholen' (Joos et al., 2006; Bakker, 2010). In Portugal, groups of schools have been encouraged to develop extended services and activities in the 'TEIP' initiative (Abrantes et al., 2013), which itself borrows from the Zones d'Éducation Prioritaires in France (Bénabou et al., 2005; Rochex, 2012). In Australia, schools have been supported in establishing links with community organizations (Gregoric, 2013). In England, meanwhile, there are 'extended' schools (Cummings et al., 2011b), and in Scotland 'new' or 'integrated' community schools (The Scottish Office, 1998).

Many of these initiatives are located in affluent countries. However, there is also a somewhat different tradition of community schooling in Africa, often supported by international organizations (Glassman et al., 2007; Miller-Grandvaux and Yoder, 2002), while some of the countries of central and eastern Europe have also been supported in developing community schools (International project 'International Standards for Community Schools: Strengthening the National Capacities,' no date). Moreover, although many of these initiatives are relatively recent, some places have a long history of schools with extended roles. In the USA that history can be traced back at least as far as the work of Jane Addams and John Dewey in the late nineteenth and early twentieth centuries (Benson et al., 2009), while in England the first recognizable community school initiative took the form of the Village Colleges developed in Cambridgeshire in the 1920s (Morris, 1925).

While this long history and extensive geographical reach makes it tempting to think in terms of a coherent movement, this would be misleading. Types of schools which at first glance appear to be similar, and which may even be labeled in the same way, can in fact be organized differently, can develop different practices, and, above all, can be based on very different rationales. The initiatives listed above, for instance (and there are many more), are concerned variously with making good shortfalls in state educational provision, involving communities in democratic processes, tackling the personal and social problems experienced by disadvantaged children in affluent countries, or ensuring the viability of rural communities. Some of them place an emphasis on community ownership of the school, others on colocating noneducational services on the school site, and others again on developing the school as a community resource. Moreover, even within the same initiative and the same broad purposes, individual schools are likely to develop distinctive characteristics as they respond to their local contexts (Cummings et al., 2011b).

This variability poses significant challenges in terms of building up a shared knowledge base on schools working with an extended role. If we cannot say what such schools are and how they operate – indeed, if there is no internationally agreed designation of such schools – it is difficult for one initiative to learn from another, and much of what we think we know may turn out to be illusory. However, while we may not be able to articulate a clear definition of what such a school 'really is,' we can at least map out some of the broad distinctions between different ways of thinking about how schools can extend their roles.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.92130-5

Competing Rationales

An important set of distinctions is around the underpinning rationales for schools going beyond their core academic business. Although these rationales are extremely varied, it is useful to think in terms of a broad difference between deficit- and asset-based approaches (Foot and Hopkins, 2010). The former focus on the role schools can play in tackling the problems experienced by disadvantaged children, families, and communities. The latter focus on building upon the assets already available in the areas they serve so that those areas become better places to live and the people within them are able to live better lives.

The rationale for deficit-based approaches was articulated most clearly by Joy Dryfoos, one of the pioneers of 'full service' schools in the USA. In disadvantaged areas, she argued:

> … schools are failing because they cannot meet the complex needs of today's students … The cumulative effects of poverty have created social environments that challenge educators, community leaders, and practitioners of health, mental health, and social services to invent new kinds of institutional responses.
>
> Dryfoos, 1994, p. xvii

In such circumstances, a focus on the academic aspect of education alone is futile, since the other needs of children will undermine whatever the school seeks to achieve in this respect. Likewise, in the face of the complexity of these needs, there is little point in tackling problems in isolation from each other. Some form of coordinated approach is needed, which in turn implies that traditional models of service delivery through separate agencies are likely to be ineffective. There is therefore a role for the school in developing new models by extending the services it can offer from its own resources and by developing strong partnerships with other agencies. As the Coalition for Community Schools in the USA suggests:

> [These] schools recognize that many factors influence the education of our children and that various conditions need to be in place to produce positive results. This is why they work with partners to mobilize the assets of the school and the entire community to improve educational, health, social, family, economic, and related results.
>
> Shah et al., 2009, p. 9

It is probably true to say that some version of the deficit-based approach underpins the majority of attempts to extend the role of schools. This is particularly the case in affluent countries where education systems are struggling to tackle inequalities in outcomes between children experiencing disadvantage and their peers (OECD, 2012). However, such a rationale does not explain the emergence of community-managed schools in economically poorer countries, nor the focus on democratization through community involvement in countries undergoing political transformation. Such initiatives are more about enhancing the assets available to communities than providing services to tackle the problems besetting children. Moreover, even in affluent and politically stable countries asset-based approaches are occasionally evident, particularly where the pressures from relative disadvantage are not the focus of schools' work. The SchoolPLUS initiative in Saskatchewan, Canada, for instance, is based on a set of liberal values and is about enhancing quality of life and community relations (M. Tymchak (chair) Task Force and Public Dialogue on the Role of the School, 2001). As Regnier argues:

> The creation of new family, community, school, and agency relationships within the SchoolPLUS model can develop forms of working relationships with rootedness that sustain the belonging needed to explore possibilities and test limits in supportive, nourishing, and forgiving contexts that advance the best developmental interests of children and youth.
>
> Regnier, 2012, p. 76

The emphasis here is on nurturing environments for children and, more generally, on enabling citizens to live a good life rather than on tackling the social problems produced by inequality.

There is, of course, no reason why schools should not combine these two rationales in various ways. Harkavy et al. propose a definition of 'community schools' which sees them both as tackling the presenting problems of disadvantaged areas and energizing the democratic processes in such areas:

> 'Community schools' bring together multiple organizations and their resources not only to serve and educate young people but also to democratically engage all members of the community in which the school is located. Essentially, this idea extends and updates John Dewey's theory that the neighborhood school can and should function as the core neighborhood institution – one that provides comprehensive services and galvanizes community institutions and organizations to help solve the myriad problems individuals and communities confront in a rapidly changing world.
>
> Harkavy et al., 2013, p. 526

While such combined rationales are clearly possible at the level of rhetoric, whether such a combination undermines one or both of the rationales in practice is an open question.

Scope

A second dimension along which efforts to extend the role of schools can be differentiated is in terms of their scope, and specifically, the extent to which they focus on the perceived needs of their students or work also with family and community issues. Some are interested primarily in improving outcomes for school students. There are, for instance, many initiatives internationally which, like the 'all-day schools' in Germany (Stecher and Schüpbach, 2013), are concerned primarily with offering out-of-school-hours arts, sports, and leisure activities, or even more narrowly with offering additional opportunities to study. Other initiatives, such as City Connects, originating in Boston, USA (City Connects, 2011) add to this basic package a range of health, social, and educational services, although the focus remains on helping students achieve more educationally. Others again include

work with families, with adult learners, or with whole communities. Hence, the Harlem Children's Zone in the USA (The Harlem Children's Zone, 2009) and its variants elsewhere (Dyson et al., 2012) offer comprehensive packages of support to children, their families, and communities. The core aim may remain that of enabling school students to achieve, but at some point this becomes inseparable from enhancing their development more generally, supporting families, enriching the lives of local residents, and promoting community development and regeneration.

As the scope of initiatives expands, so typically does the range of partners involved. While schools may be able to manage some limited additions to their core provision themselves, more ambitious initiatives involve partnerships with other public, private, and voluntary agencies. These may begin with agencies providing services directly to children, such as psychologists, mentors, youth workers, and health workers. However, they expand to include family workers, community workers, and those responsible for the resources and well-being of local areas, such as housing providers, police, employers, and economic development agencies. As this happens, the individual school may well cease to be central to initiatives and becomes one among many partners. Very probably, area governance structures emerge to manage an area-level approach.

We can see this kind of expansion clearly in developments which took place in England during the 2000s. A series of initiatives based on individual 'extended schools' gave way to 'extended services' in which schools in an area operated as a cluster to offer a wider range of services (DfES, 2005). Typically, these clusters formed part of an extensive network of child and family services at area level managed by local authorities which, in some cases, were themselves linked to area regeneration strategies (Cummings et al., 2011a). All of these services were expected to pursue a common set of outcomes for children which went well beyond educational achievement and addressed health, safety, economic well-being, and citizenship (DfES, 2003).

It is possible to see the movement along this dimension as an inevitable progression through successive generations of initiatives as policy makers and practitioners learn more about the possibilities of schools' extended roles (Lawson, 2013). It is certainly the case that, as the distal factors which promote or inhibit educational outcomes become clearer, initiatives are likely to address issues ever-more distant from the school's core academic business. However, the variety of rationales and assumptions underpinning initiatives means that it is sometimes necessary to see different ones as pursuing different aims, rather than necessarily as learning how to pursue a common aim more effectively.

Evidence for Outcomes

Attempts to extend the role of schools involve considerable effort and expenditure of resource to enhance and reorganize services. Estimates of the cost of full service schools in England suggested that schools might be using resources up to the value of £2 m ($3.25 m) to support their work (Cummings et al., 2007, p. 134 ff.). It is therefore important to know what impacts these initiatives have on outcomes for children – and, where they are involved – for families, and communities.

Unfortunately, robust evidence on outcomes is difficult to come by. In part, this is because of the inherent difficulty of evaluating complex initiatives with multiple aims, implemented in the open and unstable environments of schools and areas. There are particular issues where schools are pursuing broadly asset-based approaches and are thus aiming at outcomes where few ready measures exist. Not surprisingly, therefore, most evaluations focus on the outcomes achieved by initiatives focusing on overcoming the effects of disadvantage. Even where this is the case, however, evaluation demands sophisticated and complex designs, and needs to track initiatives over a sufficient length of time for outcomes to become apparent (Dyson and Todd, 2010). Funders have often been reluctant to invest in such costly ventures and evaluators have tended to content themselves with snapshots of those outcomes – usually in relation to children's attainments – that are closest to hand (Henderson and Mapp, 2002; Wilkin et al., 2003).

Despite these limitations, there is something of a consensus that the outcomes of schools with extended roles are, at the very least, promising. Reviewing a range of 'community school' initiatives, Blank et al. (2003) conclude that they can produce positive outcomes in four areas:

> *Student learning*: Community school students show significant and widely evident gains in academic achievement and in essential areas of nonacademic development.
> *Family engagement*: Families of community school students show increased stability, communication with teachers, and school involvement. Parents demonstrate a greater sense of responsibility for their children's learning success.
> *School effectiveness*: Community schools enjoy stronger parent–teacher relationships, increased teacher satisfaction, a more positive school environment, and greater community support.
> *Community vitality*: Community schools promote better use of school buildings, and their neighborhoods enjoy increased security, heightened community pride, and better rapport among students and residents (Blank et al., 2003, pp. 1, 2, emphases in original).

However, this optimistic assessment needs a little unpicking. There is reasonably robust evidence that the 'components' of such extended approaches – such as family support, out-of-hours activities, and social and health interventions with children – can have positive impacts on specific outcomes for children, families, and communities (Dyson and Kerr, 2013; Heers et al., 2011). There is also evidence that school improvement efforts as part of an overall change package which includes the development of an extended role can have major impacts on school performance, and therefore on the educational attainments of children within schools (Dobbie and Fryer, 2011; Whitehurst and Croft, 2010). However, it is less clear that there is a multiplier effect from combining school improvement reforms, services, and activities in a holistic 'approach.' It is difficult to find convincing evidence that there is a community school or extended school 'effect' over and above the effects of the individual services and activities on particular outcomes.

Set against this is the caveat that interventions have tended to look for these multiplier effects in relation to educational achievement and other closely related educational outcomes rather than across the broad domains across which schools may be working. Certainly, there is evidence that interventions in one domain (such as health) can have impacts on outcomes in another (such as educational attainment) (Dyson and Kerr, 2013). Moreover, it seems likely that different aspects of the work of schools interact with each other so that, for instance, efforts to improve teaching and learning need work with families and communities in order to be maximally effective (Bryk et al., 2010). Looking for additive impacts on outcomes from each additional activity undertaken by a school may therefore be less illuminating than trying to understand how extended activities create the conditions under which actions more directly related to measurable outcomes can work. Without better evaluations it is impossible to be certain on these matters. In the meantime, however, it is reasonable to conclude that schools developing an extended role are likely to have positive impacts across a range of domains, but that they need to adopt a thoughtful approach in deciding how, precisely, that role will be configured, and need to monitor carefully the outcomes that result.

Two Wider Issues

Given the diversity of initiatives, it is entirely possible for the development of extended roles in schools to have rather limited aims and limited impacts on the nature of schooling. The addition of some out-of-hours tuition or the services of a health worker to a school is unlikely to trouble other aspects of the schools' work or to have significant impacts on the communities served by the school. However, more ambitious initiatives clearly have much wider implications. There are two in particular which deserve attention.

The first is the implication of schools' extended roles for the nature of child, family, and community services. Traditionally, such services have tended to operate separately from one another, coming together only for specific purposes (Brown and White, 2006). As schools take on extended roles, however, they increase the opportunities for interagency collaboration and effectively blur the boundaries between services. Ultimately this may lead to the kind of holistic approaches, suggested by the Harlem Children's Zone and the Every Child Matters agenda in England, that are predicated on collaborative action, shared outcomes, and area-level coordination. In turn, this has implications for whether schools are seen as purely educational institutions or as multidimensional organizations engaged in many aspects of the lives of children, families, and communities. Ultimately this raises questions about the nature and purpose of education (Fielding and Moss, 2011; Moss and Haydon, 2008).

The second is the implication for the relationship between schools and the children, families, and communities they serve. In their educational role, schools enjoy considerable power in, for instance, requiring attendance, imposing sanctions on behavior of which they disapprove, and determining what shall be taught. However, as they extend their roles, the balance inevitably shifts away from compulsion toward the offering of opportunities and services. If, moreover, schools adopt an asset-based approach, their dominant position becomes increasingly untenable and they need to develop 'relational power' (Warren et al., 2009) in which decision-making is shared collaboratively between professionals and those they seek to serve. Not only, therefore, does the extended role of schools give rise to questions about the nature and purpose of education, it also raises questions about the appropriate relationship between educational institutions and those on whose behalf they are supposed to work.

Some Conclusions

The history of schools' efforts to develop extended roles is a long but somewhat patchy one. Different initiatives in different places have sought to develop different versions of an extended role, based on different aims and assumptions. Not surprisingly, the evidence base is less robust than might be hoped, and there is a clear need for more sophisticated evaluations. Nonetheless, such evidence as exists is promising and there are good reasons for persevering with efforts of this kind. However, in order to avoid simply repeating the past, these efforts have to be undertaken in full knowledge of the multiple directions in which extended roles can develop and with an awareness of the more fundamental questions that are raised as schools change the way they work. At a time when many countries are troubled by their standing in international assessments of educational performance, and by the low attainments of their most disadvantaged students, it is perhaps inevitable that many initiatives will be narrowly conceived as remedial interventions. While this is a limited view of what extending the role of schools can achieve, it is at least a start. The challenge for policy makers and practitioners is to move beyond this to a more open exploration of what schools might be for.

External Validity

Laura C Leviton, The Robert Wood Johnson Foundation, Princeton, NJ, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

External validity assesses the extent to which a causal relationship can be generalized to and across populations, settings, and treatment and measurement variables. External validity is almost wholly dependent on information outside of single studies, requiring judgments about the plausibility that results generalize beyond single studies. A confident assessment of external validity requires examination of a body of evidence from other research (causal and descriptive), from experience, and in applied settings, from reflective practitioners. Three frameworks permit assessment of external validity. The first is sampling across units, treatments, observations, and, where feasible, the larger social context. The second is decision making under uncertainty, in which prior information and judgments are used to assess the plausibility of generalization. The third is the probing of complex interactions that can obscure or illuminate the assessment of similarity across samples and studies.

Definition and Challenges

External validity (along with statistical conclusion validity, internal validity, and construct validity) provides a framework to conduct and interpret empirical studies of causal relationships. External validity assesses 'to what populations, settings, treatment variables, and measurement variables can (the effect) be generalized?' (Campbell and Stanley, 1966, p. 5). External validity was later redefined as assessing 'whether the causal relationship holds over variation in persons, settings, treatments, and measurement variables' (Shadish et al., 2002, p. 20). Rules for inference about external validity decrease uncertainty that a cause–effect relationship holds under particular conditions *outside* a single study. External validity is not defined by the *extent* to which a cause–effect relationship generalizes across conditions, any more than internal validity is defined by low p values or large effect sizes. After all, when we know that a causal relationship does not generalize, the information is useful to refine theory or to prevent the useless expenditure of resources, just as internally valid information on the absence of an effect is useful for these reasons. Sometimes researchers apply the term 'external validity' to correlational studies; however, this article will deal only with the external validity of causal relationships. Historically, researchers have faced three challenges in assessing external validity.

The Challenge of Inductive Inference

External validity requires inductive inference, relying on the accrual of studies and extrapolation beyond the conditions and findings of a single study. Inductive logic about causation is never fully justified (Campbell and Stanley, 1966) (*see* Generalization: Conceptions in the Social Sciences). By contrast, internal validity is established through a more deductive framework whereby causal relationships can be both corroborated and falsified within a single study (*see* Internal Validity). Both internal and external validity depend on information that originates outside the single study, especially regarding judgments about what is already known. However, external validity is much more dependent on information from outside the study.

Perceived Trade-offs between Internal and External Validity

Internal validity is compromised if research does not involve controls and the measurement of outcomes. But many researchers are concerned that the artificiality of such studies does not reflect prevalent real-world conditions (e.g., Barker, 1968; Brunswik, 1955). External validity can often be compromised by the very presence of design controls, obtrusive measures, and restricting the study to respondents who are willing to receive any treatment to which they might be assigned. Researchers concerned about external validity have divided into those who set less priority on the study of causes, in general, and those who would maximize external validity by studying causal relationships in field settings. Some researchers put a higher priority on internal validity, arguing that there is little point in generalizing a causal conclusion about which there is legitimate doubt (Campbell and Stanley, 1966; Cook and Campbell, 1979). Others maintain that external validity deserves priority because the research should be a reflection of prevalent real-world situations, especially those that involve testing the value of educational, public health, and social services (Cronbach, 1982). The challenge then arises: What is the best balance in a given study? Cannot both internal and external validity be optimized somehow?

The Challenge of Complex Interactions

Causal relationships in real-world settings are at the very least complicated and often dynamic and complex (Rogers, 2008). Statistical interactions of variables are assumed to be pervasive (e.g., Brunswik, 1955; Cronbach, 1982). This means that the strength of a causal relationship is assumed to vary with the population, setting, or time represented within any given study, and with the researcher's choices about treatments and measurement of outcomes. Without a sensitive assessment of such interactions, true effects can be obscured or causal claims can be overgeneralized to a wider range of people, settings, times, treatments, or outcome constructs than is warranted. Unfortunately, the number of possible interactions is often endless (Cook, 1993). The challenge is: How do we cope with complexity?

A practical first step is to assess some generic interactions that are both frequent and plausible to explain variation in outcomes and the interpretation of causal relationships. Interactions occur often between treatment, populations, measures, and context, posing plausible *threats to external validity* (Campbell and Stanley, 1966; Cook and Campbell, 1979). Because external validity specifies the conditions under which an internally valid relationship can be reproduced, threats to external validity necessarily invoke internal validity.

The interaction of testing and treatment suggests that an effect size varies by the conditions of measurement.

The interaction of selection and treatment hypothesizes that an effect size varies by population studied.

The interaction of setting and treatment describes effects that vary by setting.

The interaction of history and treatment deals with the extent to which a causal relationship replicates across different times and events.

Other interactions between features of the study and treatment sometimes occur, but their plausibility depends on the individual study context and on what is generally known about these study features (*see* Internal Validity).

External Validity Involves Inferences from Samples

Generalizing from Single Studies to Samples, Classes, Categories, and Constructs

The statistician would say that researchers generalize about a sample they have observed of a population, usually of persons or other units being studied. However, external validity treats inferences about treatments, measures, and settings just as seriously as inferences about human population groups. It therefore assumes that studies have to sample from these domains as well as from populations (Cook, 1993). A given study therefore represents not only a sample from a population of units but also a sample from a universe of potential settings, a universe of potential treatments, and a universe of potential measures. The sampling frame becomes explicit whenever an investigator makes choices about whom to study, what treatment to administer, or which measures upon which to base inferences. Beyond the individual study, bodies of research (literature reviews, meta-analyses, and programs of related studies) are now understood to be samples from the universe of potential studies. The available sample of findings both limits and guides inferences about external validity.

The sampling frame for external validity considers not only categories but also theoretical constructs (Cronbach, 1982). Construct validity is therefore intimately tied to external validity. This becomes clear when we note that a population of persons is akin to a category of persons; treatments often represent a set of underlying principles that are made operational in a given study; settings can be classified into those that facilitate or impede access to the population and moderate the 'dose' or fidelity of treatment; and outcome measures often reflect bigger, more general underlying constructs, such as 'access to medical care' or 'youth resiliency.' Specifying these larger classes, categories, and constructs is necessary to justify a generalization about causal relationships (Shadish et al., 2002).

Methodologists have adopted the following notation from Cronbach (1982). Uppercase notation represents the universe or domain, while lowercase represents an element in a specific study. We will use the prevention of HIV/AIDS to illustrate.

U represents the population of units (persons, sites, communities, organizations, states, nations, or other settings and aggregates) about which a conclusion is sought. In contrast, *u* refers to the sample of units in a study. Thus, 'people at high risk of HIV infection' include men who have unprotected sex with men, injection drug users (IDUs) and their sex partners, sex workers, runaway homeless youth, and, internationally, communities where HIV infection is prevalent.

T represents the plan and the set of realizations for a treatment, experimental manipulation, program, or other intervention, while *t* is the single realization of *T* for a given *u*. In 2012, there were over 100 evidence-based programs for HIV prevention, most of which include a core of common behavioral principles. Yet to be effective, a realization of *T* must be adjusted to be relevant to the community's situation. A naturally occurring event can also be denoted *t*, such as a celebrity announcing that he is HIV infected, and *T* is the set of similar events.

O represents the admissible procedures and conditions for obtaining data (and the data themselves). In causal research, it is often used to refer to the possible effect, thus using *O* to represent the outcome construct and *o* the actual measure of effect. HIV prevention commonly uses self-report and partner report measures, supplemented by unobtrusive measures such as condom purchases or redemption of vouchers for condoms.

S represents the context or setting, including the culture and times in which the study takes place. Some researchers use *s* to denote an individual study's setting and *S* to denote the accrual of such settings (Campbell and Stanley, 1966). Others maintain that *S* is always confounded with *U* and *T*, and cannot be deliberately sampled in the same way as *U*, *T*, and *O*. The debate becomes clear in HIV prevention, where the passage of time (*S*) has led many individuals at risk (*U*) to become complacent, requiring a different realization of *T*. Also, *T* is most effective when communities (*U*) trust the organizations (*S*) that carry out *T*. Yet these organizations vary in their capacity to carry out *T*, thus affecting the realization of *t* (dose or fidelity of the treatment).

UTOS is the domain about which a research question is asked. Once *U*, *T*, *O*, and *S* are specified concretely, that constitutes a description of the causal question being researched. In contrast, an individual *utoS* is the combination of *u*, *t*, and *o* that constitutes an instance on which data are collected. Thus, it is the operational or sampling level of a study; it is how the researcher proposes to answer the question about *T* as a cause, *O* as an effect, *U* as a population of persons, and *S* as the cultural and historical contexts in which the hypothesis is tested.

Within *UTOS*, replications are of three kinds: (1) exact replication using fresh samples of *U*, *T*, and *O*; (2) studies by other investigators trying to repeat the *UTO* procedures according to the best description available; and (3) conceptual replication by other investigators who choose different procedures to represent the same *U*, *T*, and *O* based on their own judgment about what constitutes instances of each. In all three

cases, the interest lies in ascertaining whether a class of causal relationships was replicated. For example, the policy maker may want to know whether a treatment for IDUs in New York City will produce a reduction in behaviors that lead to HIV transmission. Replication of the treatment across fresh samples of IDUs in New York and other northeastern cities increases confidence about treatment effectiveness.

At the level of *UTO*, the instances are joint distributions of units, treatments, and observations. However, some combinations are more common than others. For instance, most HIV prevention studies initially used testing and counseling approaches offered through highly trusted organizations to gay and bisexual men in the United States. Later on, a wider range of organizations addressed additional groups at risk, adding social marketing and community-based interventions to testing and counseling. By studying categories within these joint distributions, called sub-*UTOS*, we may ask whether a causal relationship holds with different categories within *UTOS*. These lower order categories often include characteristics of the populations, variations in the content or level of a treatment, or dimensions of some set of measured responses. For example, one may study behavior changes in IDUs versus women in African villages, or in cases that experience a treatment at high and moderate levels of intensity and duration. Sub-*UTOS* provide a key to external validity because patterns of variation within and across studies allow us to ascertain some of the conditions under which a causal relationship holds.

Inferences about *UTOS* are both retrospective and prospective. They rely on replication studies that already exist and on a definition of constructs that incorporates these studies. Generalization from *utoS* to *UTOS* is not entirely bound by the existing studies, since inferences sometimes need to be made about levels of variables that were not directly observed, for example, when fourth-grade and sixth-grade children are studied, but not those in the fifth grade, or when 4 h of therapy are given versus 8 h. Moreover, a critical understanding of variation in *UTOS* always depends on construct validity and on theory building, which usually go beyond the observed *utoS*. Nevertheless, at some point causal hypotheses undergo a test that then extends external validity to new variations within *UTOS* – or expands *UTOS*. By contrast, other questions about external validity concern new domains that were not studied, and these are entirely prospective, or even speculative.

Generalizing from Existing Studies to New Domains

Cronbach (1982) distinguished two basic types of external validity inferences: those concerning the reproducibility of findings in *UTOS*, and those that go beyond *UTOS* to new domains termed **UTOS*. The asterisk indicates that causal relationships in these domains have not yet been studied, or have not been studied jointly. Inferences about **UTOS* pose challenges above and beyond those in *UTOS*, whether the finding involves an important relationship in basic social science or the effect of a social program or policy. Uncertainty is much greater about whether the causal relationship holds in **UTOS*. Take the example of HIV prevention: results may impress policy makers who are looking for ways to combat the global epidemic. Will social marketing of condoms, when modified for use (**T*) with village women in another country (**U* and **S*), also lead to reductions in the (very different) behaviors that put them at risk of HIV transmission (**O*)? This requires asking whether the cause–effect relationship generalizes to **UTOS*. The answer is not definitive until cause-probing studies of **UTOS* are conducted.

Decision makers and practitioners in education, public health, and social programs face acute uncertainties about such issues all the time, and increasingly call for better ways to cope (Glasgow et al., 2006). The key is to find new ways to reduce uncertainty. There is always some uncertainty about causation in the social sciences, since plausible alternative explanations may be discovered for even the best replicated cause–effect relationship (*see* Internal Validity). However, uncertainty increases about the conditions under which causal relationships hold, as investigators move from an observed set of *utoS*, to unobserved variations within a well-defined *UTOS*, to **UTOS* (Cronbach, 1982).

Bayesian statisticians offer a useful way to cope with uncertainty about generalization: first incorporate information to assess the prior likelihood that a finding will generalize, assess the degree of uncertainty about the prior likelihood, and assess the likely consequences of a decision about generalization that is correct or incorrect (Cronbach, 1982). Where the consequences are important (expenditure of public resources, a prevalent challenge for implementing *T*, or a new direction for theory), new information is needed. After a decision is taken, additional information becomes available: either a test of causal relationships or descriptive and experiential information that may help to further reduce uncertainty.

Studies to Reduce Uncertainty about *UTOS* and **UTOS*

Inferences about external validity can proceed only so far in the context of a single study. The challenges can be addressed more adequately through literature reviews and programs of studies, planned or unplanned. Multiple studies allow us to improve the *quality* of inductive inference about external validity. They also permit us to recognize potential trade-offs between internal and external validity and to *optimize* both (where feasible). Finally, they improve our ability to *disentangle the web of interactions* among variables and so identify more of the conditions under which a causal relationship varies in magnitude and even sign.

Ideally, we would choose a sampling frame to represent the universe of all possible versions of *utoS*. The advent of 'Big Data,' in which so much data about social phenomena are being captured, may some day permit this (McAfee and Brynjolfson, 2012). For example, the Obama 2012 campaign conducted over 100 randomized experiments on donating through social media at fairly low cost. However, most causal studies in the social sciences operate under conditions that prohibit representative sampling. Concerning *S*, we cannot sample historical occasions at random, and expense usually prohibits choosing a random sample of all relevant social situations in order to implement a treatment therein. Certain *u* are inaccessible to us, or we are prohibited from studying them in certain ways. Moreover, a sampling frame – of any kind – implies that we know the dimensions of greatest relevance for *UTOS*; in many cases, however, we do not.

A pragmatic alternative approach is to use the less sophisticated methods and principles typically used for generalizing from operational representations of a cause or effect construct. Social scientists routinely generalize from *t* to *T* and from *o* to *O* without random sampling, and they seem to feel very confident about the inferences they draw because the *constructs* make logical sense. Shadish et al. (2002) identified five principles that scientists use in making generalizations. We first present the principles, then the implications for generalizing about a body of evidence.

Five Principles to Generalize about Causal Inferences

1. *Surface similarity*. Some *utoS* look like the *UTOS or *UTOS* to which one would like to generalize. This process is known as pattern matching (Campbell, 1988). Prior theory and other forms of consensus in social science help to identify prototypes and principles with which to classify groups (*U*), treatments (*T*), measures (*O*), and settings (*S*) (Berkowitz and Donnerstein, 1982). Just as the early naturalists classified birds, so social scientists can begin to classify and generalize about *UTOS*.
2. *Ruling out irrelevancies*. Across many studies, there is both relevant and irrelevant variation in *UTOS*. Variation is irrelevant when it does not change a causal generalization. Thus, a treatment might be implemented in different ways, only some of which matter; outcomes might be measured in different ways; and the demographics of respondents might differ even though they all belong in the category about which one wants to generalize. Variation in *UTOS* provides an opportunity to test whether a causal relationship holds across the irrelevancies actually sampled (Cook, 1993; Kruglanski and Kroy, 1976). It is therefore a test of whether the relationship is robust despite irrelevancy in how measurement occurs, a treatment is operationalized, a sample is drawn, and settings are selected. For example, we know that various groups at risk of HIV/AIDS (*U*) respond well to messages delivered by people similar to themselves (*T*), although the venues vary tremendously (e.g., street, classroom, bar, and homeless shelter), and the specific risk behaviors (*O*) vary as well. The risk behaviors form a larger class, as do the populations and treatments, and the findings replicate across cultures and decades (*S*). For generalizing to **UTOS*, this robust type of finding is also helpful. Given the consistent findings, what is the prior likelihood that a new group at risk of HIV/AIDS (**U*) would also change risk behaviors when exposed to an exemplar of *T*? It is certainly not zero.
3. *Making discriminations*. Certain features of *UTOS* help us to limit generalizations and thus sharpen and better define *UTOS*. This is especially the case when similar concepts can be differentiated with respect to a causal relationship. So for example, one has to be explicit about how liking differs from love, or how one school reform program differs from another. For generalization about *UTOS*, one has to demonstrate empirically that the causal proposition one wants to defend holds for one concept and not another similar concept. Both theory and measurement are needed to support the discrimination required. To differentiate what can be generalized in **UTOS*, boundary variables are helpful; these are defined as 'critical differences between the research setting and criterion setting which could alter the existence or magnitude of the relationship between two or more variables' (Bernardin and Villanova, 1986, p. 43). For example, HIV prevention is unlikely to work when provided through organizations that do not have the training and supervisory capacity to implement it well (Miller et al., 2003).
4. *Interpolation and extrapolation*. Few social or behavioral theories succeed in specifying the levels of a treatment that will usually bring about a desired effect. Parametric studies that vary many levels on the independent variable and then examine response curves are rare: instead, just two or three levels are manipulated, leaving us unclear about how the outcome variable would have behaved at points between or beyond the levels measured. In principle, such interpolation is easy. For generalizing about *UTOS*, it is desirable to sample a wide range of treatment levels and as many points in between as are feasible. In the same way, we might sample a wide range of persons (e.g., on age or educational attainment), time periods (e.g., years after discovery of the AIDS epidemic), and levels of outcome variables that might otherwise be truncated. Again, 'Big data' may eventually free external validity from this limitation (McAfee and Brynjolfsson, 2012)

Extrapolation of effects that are beyond the ranges available in studies is more problematic, because the shape of the curve or the nature of the effect itself may change at more extreme values on the independent variable. Thus, water turns to ice at 0 °C and to vapor at 100 °C. Between these points, it is water. But few social science relationships understood this well. We simply do not know where qualitative transformations come about in many social relations (e.g., how much life stress is needed to create clinically significant depression). Extrapolation to points closer at hand (*UTOS*) is generally less uncertain than extrapolation to more distant points (**UTOS*).

5. *Causal explanation*. One of the major goals of science is to explain phenomena, including causal relationships. Identifying the how or why of a relationship helps to replicate or extrapolate about the relationship, even in circumstances that are quite different. For instance, knowing why key messages cause people to protect themselves from HIV infection might help to adjust these messages to meet new circumstances over time. This is why causal explanation is held to be the major mechanism for moving from *utos* to **UTOS*, for generalizing to as-yet-unstudied circumstances (Cronbach, 1982). Thus, we judge social and behavioral theories by their capacity to specify constructs that moderate or mediate a causal relationship. However, it is rare to find studies that have manipulated all of these causal-explanatory contenders or even a goodly portion of them. Some are usually measured, though, and so it becomes important to use measurement and data analysis to establish which components are most likely to be causally responsible for an effect and so are essential to any practical generalizations that will be made from the data.

Using the Principles to Generalize from a Body of Evidence

Using these five principles, generalizations about *UTOS* can be made from existing research and through purposive sampling of new *utoS*. For extrapolating to **UTOS*, the research community

uses prior information and best judgment to determine the plausibility or implausibility of generalization (Cronbach, 1982).

In order to utilize the five principles for external validity, literature reviews and meta-analyses need to be thoroughly informed about the details of each *utoS*. It is on this basis that readers can be confident about the surface similarities of studies, the irrelevancies, and the features that discriminate key concepts. Yet many meta-analyses cannot go beyond the very surface of surface similarity, because the journal articles and other materials on which they rely do not provide enough detail, particularly about context and implementation (e.g., Ogrinc et al., 2008). Sometimes the details of *utoS* can have great importance – quality of implementation, for example (Lipsey, 2009). Also, causal explanations may emerge only as the body of research grows, and it is seldom possible to go back in time to study new mediators or moderators of the effect. In addition to these limitations, Shadish et al., (2002) offer a host of threats to the external validity of literature reviews, including sampling bias in *UTOS*, restricted variation in *UTOS*, failure to test for heterogeneity in effect sizes (which might lead to a premature conclusion that the effect is generalizable), lack of statistical power for studying sub-*UTOS*, and restricted variation in the irrelevancies that give confidence that the cause–effect relationship is a robust one.

A plan for new studies to probe external validity will sample purposively from the range of possible *utoS* based on surface similarity, by selecting modal or typical instances. Purposive sampling can offer a stronger test of external validity by introducing as much irrelevant variation as possible. And by sampling for specific cognate concepts, planned studies could help discriminate the limits of the causal relationship. With regard to interpolation and extrapolation, the Multiphase Optimization Strategy may be helpful (Collins et al., 2011). It uses preparatory steps to select varying doses of real-world social and health interventions, in a way that culminates in randomized experiments with the best potential to inform external validity. This strategy also assists discrimination by unpacking treatments and administering them with and without components that might be critical to the outcomes. Finally, causal explanation can be addressed by examining the deep or structural similarities and differences inherent in the samples of *utoS*. For example, cultural adaptation of an intervention may be required in order to include Latinos in a study; one wants to go beyond surface similarity to make sure that Latinos will respond to the adapted materials in the intended ways.

For generalizing to **UTOS*, it is necessary to rely on information beyond the corpus of cause-probing studies, by using sources such as surveys and qualitative studies. Applied fields do not generally do this very well, although good models exist. For example, social marketing in health promotion routinely employs a core set of behavioral principles, but through focus groups, rapid ethnography, and other information, the principles are systematically adapted to address the needs and concerns of the population and the setting (e.g., Leviton et al., 1999). For generalizing about the effects of social interventions, the researcher can also access the experience of expert, reflective practitioners (Schön, 1984). It is noteworthy that discussions of external validity in social programs almost completely exclude practitioners' opinions. Yet reflective practitioners have seen many examples of *utoS* or **utoS*, and as experts in service provision, they will perceive patterns in *UTOS* that the researcher does not recognize. Expert practitioners often have theories in use that can be elicited and utilized on behalf of external validity – an issue of particular importance for the quality of implementation, and for assessing complex and emerging contexts. In applied areas, all these sources of information can be incorporated into theories of change or logic models to assess the plausibility of achieving an effect in a particular **utoS* (Leviton et al., 2010). For example, condom promotion for HIV prevention may be unworkable in certain cultures – or must be greatly adapted to be feasible. Just as alternative explanations can be ruled out to assess internal validity, such information helps the decision maker rule out certain **utoS* with a fair degree of certainty ('You can't get there from here'). Thus, the limits of generalizing about **UTOS* are further described; the challenge comes in *ruling in* **utoS*!

Descriptive information and reflective practice can be equally useful after the fact. In the absence of a controlled study, experience provides useful information for external validity, just as the Bayesian statistician incorporates additional information into an *a posteriori* assessment of probabilities. It is on this basis that practitioner feedback about evidence-based practices should be assessed. Where there are prevalent barriers to implementation, these need to be assessed. Where there are prevalent contexts that moderate effects, we need to know about this. Yet we do not abandon an eventual test of **UTOS*; instead, we have a much better sampling frame to maximize useful information.

Abstract

Extraversion is a term often associated with a range of human behaviors and experiences. Biological, environmental, and even developmental features have variously been identified as important contributors to variance in these. Our understanding of how these features form an overall structure is, however, still developing. Attempts to better understand extraversion as a complex, dynamic system often one means by which the breadth of knowledge accumulated thus far might be integrated.

Extraversion is a personality trait that broadly describes differences between people in their social interactions, positive emotions, impulsivity, and energy levels. A highly extraverted person is generally thought to be outgoing, energetic, enthusiastic, and positive. Someone with low levels of extraversion (sometimes called introverted) is thought to be quiet, shy, calm, and slow-paced. Extraversion has long been recognized to be an important feature of human personality. From the typologies offered by the ancient Greeks and Romans, through to the sophisticated models of today, the behavioral and experiential variance described by extraversion has been considered an important descriptor of individual differences. The paragraphs below summarize several different approaches to understanding extraversion, including psychoanalytic, psychometric, and biological approaches. Different models of extraversion are compared, real-life outcomes associated with extraversion are described, and future directions in extraversion research considered.

Historical Overview of Extraversion

Ancient Typological Accounts

The earliest descriptions of personality were those of Hippocrates and Galen, who proposed that people could be classified as one of four personality types, each associated with a physical element: sanguine (air), choleric (fire), melancholic (earth), and phlegmatic (water). Each type was associated with particular physical features. Both sanguine and choleric types contained elements now considered aspects of extraversion. Sanguine types of people were social, expressive, and positive in outlook. Choleric types were energetic, wilful, and passionate.

Psychoanalytic Accounts

The earliest personality model to explicitly describe extraversion was Jung's analytical psychology. He proposed 16 personality types, these being combinations of four more basic, dichotomous sets of individual characteristics: extroversion/introversion, sensing/intuition, thinking/feeling, and judging/perceiving. According to Jung (1916), for each of these dichotomous pairs, individuals could be classified as one or the other: extrovert or introvert, judger or perceiver, and so on. This means that while Jung regarded extroversion to be a fundamental aspect of human personality, he described it as one that characterizes some, but not all people. Those who are not extroverts, Jung described as introverts. The fundamental distinction between these targeted differences in the value individuals attach to external versus internal stimuli. These differences were thought to account for important differences in how people behave. Thus, extroverts were thought to primarily value the external world, causing them to direct their energy outward. Introverts, on the other hand, were thought to primarily value the internal world, leading to an inner focus. Jung's theory formed the theoretical basis of the extraversion/introversion classification in the widely used Myers-Brigg's Personality Test.

Early Lexical Accounts

In contrast to the earlier approaches, the lexical approach to personality viewed extraversion as a quality that all people possess to different degrees. This is a dimensional approach rather than a typological approach to personality. The lexical approach uses everyday language as its starting point. The premise of this approach is that important psychological traits are likely to be encoded in everyday language. For example, the existence of trait adjectives such as 'energetic,' 'positive,' and 'excitable' suggests that differences in these traits provide useful information about what people are like. Allport and Odbert (1936) identified over 4500 such adjectives within the English language. Cattell (1943) later examined this word-list using factor analysis – a statistical technique for grouping a large number of variables into a smaller number of factors, based on the strength of association. By doing this, terms that describe the primary factors in which individuals differ were identified. For example, it was noted that people's ratings of others on the terms 'happy,' 'positive,' and 'enthusiastic' were generally similar, as were ratings on the terms 'reliable,' 'industrious,' and 'consistent.' This was taken as evidence that individual differences in two factors might explain differences in how people are rated in relation to these six adjectives.

Cattell's (1945, 1947) analyses suggested that somewhere between 12 and 20 factors could account for all personality differences between people. In these early analyses, extraversion did not emerge as a single factor but was represented by several related factors (e.g., dominance, liveliness). Later factor

analyses found that five factors best explain associations among adjective ratings, and extraversion emerged as one of these five key factors (Tupes and Christel, 1961; Norman, 1963). Newer lexical models suggest a six-factor model, but still include extraversion as a key personality factor (Lee and Ashton, 2004).

Early Biological Accounts: Eysenck

Eysenck (2008/1967) believed that differences in extraversion were due to physiological differences in brain systems that caused some people to be more easily aroused than others. Specifically, he proposed that the ascending reticular activating system (ARAS) regulated arousal. People differ in the sensitivity of this system, which causes them to respond differently to their environment. A moderately stimulating environment might cause people with a very sensitive ARAS to feel overstimulated and retreat (i.e., to behave like introverts), but people with a less sensitive ARAS to feel understimulated and seek out additional stimulation (i.e., to behave like extraverts). In this model, the key characteristic of extraversion is impulsivity – social characteristics like friendliness and gregariousness were not originally considered as part of the extraversion trait.

According to Eysenck (1965), differences in extraversion predict how easily people form automatic associations. One classic experiment presented a tone and a puff of air to the eyeball several times. The puff of air caused people to blink. When the tone had become associated with the puff of air, people would blink when they heard the tone, even if the puff of air was not present. People with low extraversion were quicker to form this automatic association, possibly because they were more aroused by the stimuli in the first place. That is, extraversion moderates the ease of classical conditioning.

Further Development of the Biological Approach

Reinforcement Sensitivity Theory

Gray (1970, 1987) extended Eysenck's research on extraversion and conditioning by distinguishing between positive and negative stimuli. He claimed that extraverts may be slower to form associations only for negative stimuli (like the puff of air), but are faster to form associations when stimuli are positive. That is, conditioning is controlled by two systems: (1) one that is reactive to positive stimuli and (2) one that is reactive to negative stimuli. The system representing reward sensitivity (i.e., reactivity to positive stimuli) was called the behavioral activation system (BAS), while the system representing punishment sensitivity (i.e., reactivity to negative stimuli) was called the behavioral inhibition system (BIS). This theory is known as reinforcement sensitivity theory (RST).

According to RST, these systems control the conditioning process by differentially reinforcing particular behaviors. Thus, those with a sensitive BAS system were thought to learn more readily from positive stimuli and therefore be more prone to impulsivity. Those, however, with a sensitive BIS system were thought to learn more readily from negative stimuli and therefore be more prone to anxiety and caution generally.

By this account then, extraversion was not regarded as a fundamental personality trait. Instead, impulsivity and anxiety were considered primary, and extraversion was described as a construct that combines both. RST then described extraversion in terms of a low tendency toward anxiety (or a low degree of punishment sensitivity) and a moderate tendency toward impulsivity (or a moderate degree of reward sensitivity).

Revised Reinforcement Sensitivity Theory

RST was later revised and is now known as revised reinforcement sensitivity theory (RST-r; Gray and McNaughton, 2000). In this revision, the two basic systems of reward sensitivity and punishment sensitivity were reinterpreted to represent approach and withdrawal tendencies. Approach tendencies were still thought to be expressive of the BAS, but withdrawal tendencies were thought to be expressive of a fight, flight, freeze system (FFFS). The BIS was still a feature of the theory, but was reconceptualized as a sophisticated system that resolves conflict between the BAS and FFFS. Such conflicts were thought to occur in two circumstances: (1) when more than one positive or negative stimulus is encountered, requiring a choice between the two and (2) when both systems are activated – for example when a person is attracted to someone, but is simultaneously afraid of rejection. When such a conflict occurs, the BIS was thought to inhibit both the approach and withdrawal systems in an iterative manner until a single behavior dominates. RST-r, therefore, suggests the personality system as a whole to be both complex (made up of many parts) and dynamic (changing over time).

This new theory led some researchers to reexamine whether extraversion is a primary personality trait. Yet many studies show that measures of the BAS are strongly related to extraversion. Such results suggest that extraversion may actually be the fundamental trait for reward sensitivity (Smillie et al., 2006).

The Underlying Structure of Extraversion

Extraversion is a broad personality trait that reflects an integrated network of narrower constructs (e.g., sociability, positive affect, impulsivity, and reward sensitivity). Perhaps the first empirical exploration of the underlying structure of extraversion was the factor analysis of Guilford and Guilford (1934). They found evidence for up to 18 underlying elements of extraversion. The four most important elements represented an approach tendency, an anxiety/withdrawal tendency, impulsiveness, and self-interest.

Many different personality models include extraversion as a primary trait. However, different models propose different underlying elements of extraversion, usually referred to as facets. Table 1 compares several different faceted models of extraversion, showing the conceptual similarity between different facets. All models include sociability, which represents a preference for social interaction. There is much less consensus regarding the other facets. For example, some models propose surgency (a type of reward sensitivity that produces positive affect) as the defining feature of extraversion, whereas other models do not include surgency at all (Goldberg, 1990). Similarly, while Tellegen (1985) proposed

Table 1 Conceptual representation of the facets of extraversion in various models of extraversion

	Eysenck personality questionnaire-revised (Eysenck et al., 1985)	*Sixteen personality factor questionnaire (Cattell et al., 1988)*	*Multidimensional personality questionnaire (Tellegen, 1985)*	*Revised NEO personality inventory (Costa and McCrae, 1992)*	*HEXACO personality inventory (Lee and Ashton, 2004)*
Sociability	Sociable	Warmth	Social closeness	Warmth Gregariousness	Sociability
Dominance	Dominant Assertive	Dominance	Social potency	Assertiveness	
Social boldness		Social boldness			Social boldness
Positivity	Surgent		Well-being	Positive emotions	
Energy	Active Lively	Liveliness		Activity	Liveliness Expressiveness
Excitement-seeking	Sensation-seeking Venturesome			Excitement-seeking	
Carefree	Carefree				
Self-reliance		Self-reliance			
Achievement			Achievement		

that positivity was the defining feature of extraversion and eliminated sensation-seeking elements from his model, the recent HEXACO model does not include positivity as part of extraversion at all.

DeYoung et al. (2007) recently suggested an intermediate level between narrow facets of personality (such as impulsivity) and broad domains of personality (such as extraversion). They propose that there are two aspects that underlie each personality domain. Their model is an extension of the NEO-PI-R model of personality shown in **Table 1**. In the NEO-PI-R model, there are six specific facets that underlie extraversion: warmth, gregariousness, assertiveness, positive emotions, activity, and excitement seeking. De Young et al. propose that these can be grouped into two aspects of enthusiasm and assertiveness. Enthusiasm is an aggregate of the gregariousness, positive emotions, warmth, and excitement-seeking facets. Assertiveness is an aggregate of the excitement seeking, activity, and assertiveness. Extraversion is the only one of the five domains where a facet (excitement seeking) contributes to both aspects.

Extraversion across the Lifespan

Although the domain of extraversion appears stable over time, the lower-order facets may show systematic age-related change (Soto et al., 2011). A longitudinal study of age-related personality change in adults found that (1) excitement seeking decreases after 30 years of age; (2) activity is largely stable until 40 years of age, when it begins to decrease; (3) positive emotions and warmth increase until about 50 years of age, with positive emotions decreasing from 60 years and warmth decreasing from 70 years; and (4) assertiveness increases until 60 years of age and then decreases slowly (Terracciano et al., 2005). Cross-sectional research found that while middle-aged people and older people have similar levels of gregariousness and assertiveness, older people have lower levels of warmth, activity, excitement seeking, and positive emotions than middle-aged people (Roepke et al., 2001). These results suggest that at the facet level, extraversion continues to change across the adult lifespan.

Extraversion and Valued Outcomes

Extraversion predicts valued outcomes at work, school, and in personal life. For work outcomes, the largest effects are for leadership and job satisfaction. Of the big five personality domains, extraversion shows the strongest relationship with transformational leadership and among the strongest with job satisfaction (Bono and Judge, 2004; Judge et al., 2002). Extraversion shows a positive association with academic performance in the early years of school but a negative association in high school and university (Poropat, 2009). This may be due to the different mechanisms underlying academic achievement at different stages. For example, socialization with teacher and peers may be a key mechanism for achievement in the early years of school, whereas a preference for socializing at university may have a detrimental effect on grades. Extraversion also relates to subjective well-being, such as life satisfaction and happiness (Cooper and DeNeve, 1998).

There is some empirical evidence that different facets of extraversion show different relationships with valued outcomes. For example, a recent meta-analysis predicted job performance from the six extraversion facets and two extraversion aspects of DeYoung et al.'s (2007) aspects model (Judge et al., 2013). Both aspects of extraversion showed a small association with performance, but this was mainly accounted for by the facets of positive emotions and activity. In fact, the excitement-seeking facet was associated with poorer job performance. These results highlight even when extraversion shows a zero or very small relationship with a valued outcome; some of the underlying elements (either facets or aspects) might still be important predictors.

Extraversion: A Complex, Dynamic System?

A complex, dynamic system is one with multiple underlying features that change over time. Extraversion can be regarded as a complex, dynamic system as (1) it has multiple facets underlying the construct as a whole (i.e., it is complex) and (2) these facets change over time (it is dynamic). For this reason, extraversion might be explained in terms of Cloninger's et al. (1993) Psychobiological Model of Temperament and Character. This

model describes personality as a complex dynamic system dependent on two sets of characteristics. First, four biologically based temperaments drive personality (novelty seeking, harm avoidance, reward dependence, and persistence). Second, the expression of these temperaments is modifiable by three character traits (self-directedness, cooperativeness, and self-transcendence). These character traits describe how an individual learns and adapts to their environment. Two of the temperaments (novelty seeking and reward dependence) relate to extraversion and one of the character traits (cooperativeness) relates to reward dependence (Stallings et al., 1996; DeFruyt et al., 2000). Therefore, changes in extraversion facets across the lifespan can thus be described in terms of a dynamic system involving such temperament and character traits.

Complex, dynamic systems have many properties that set them apart from simple systems. These vary according to the type of system being theorized, but include nonlinearity (producing outcomes that are disproportionate to their inputs), fractality (having self-similar patterns), and even chaos (being determined, but unpredictable) (Gregson and Guastello, 2010; van Geert and Steenbeck, 2008). The presence of any of these three features would have important ramifications for how extraversion is understood.

However, methodologies designed to identify these or related features of complex dynamic systems have yet to be applied to research on extraversion. It is possible that a complex systems approach may be able to integrate multiple findings into a single theory, explaining developmental changes in extraversion facets, different facets' relationships with valued outcomes (e.g., workplace performance and academic achievement), as well as behavior-environment contingencies. Complex system methods may thus represent a promising new direction for identifying the structures and operations that underlie extraversion.

Abstract

Six muscles control the movements of each eye, allowing two broad categories of movements: gaze-stabilization and gaze-shifting movements. Gaze-stabilization movements act to compensate for movements of the head and body, acting to stabilize the image of the visual world on the retina. Gaze-shifting movements shift the fovea into alignment with objects of interest in the visual world. Eye movements are controlled by three cranial nerve nuclei (the oculomotor (III), trochlear (IV), and abducens (VI)), which together control the six eye muscles. The oculomotor system provides an excellent model for understanding the principles of movement control.

Eye Movements

Five types of eye movements are generally recognized.

These movements fall into two broad categories: gaze-stabilization movements and gaze-shifting movements. Gaze-stabilization movements rotate the line-of-sight to compensate for movement of the head and body, stabilizing the visual world on the retina. In the absence of these movements, visual acuity is severely compromised because visual images move across the retina whenever the observer moves through the visual environment. In almost all vertebrates, two neural systems work together to achieve gaze stabilization: the vestibulo-ocular system and the optokinetic system. Gaze-shifting movements, unlike gaze-stabilization movements, shift the fovea into alignment with objects of interest in the visual world. The three classes of movements that achieve gaze shifts are saccades, smooth pursuit eye movements, and vergence eye movements. Saccades are rapid shifts of the line-of-sight from one point in the visual world to another. Smooth pursuit eye movements allow the line-of-sight to track moving objects, slowly rotating the eye to keep a visual stimulus, which is moving across the visual field aligned with the fovea. Together saccades and smooth pursuit movements are referred to as versional movements because they cause both eyes to move in a similar direction and at the same speed. Vergence eye movements that occur only in binocular animals like humans, shift the lines-of-sight of the two eyes with regard to each other (either converging or diverging the angle between the two eyes) so that a visual stimulus can be aligned with the same point on each retina, even if that stimulus moves toward or away from the observer. In the nineteenth century, Herring proposed that only vergence movements involve the independent control of both eyes.

For all other movements, he proposed that the two eyes always receive identical movement commands. This hypothesis, which still informs our basic view of oculomotor control, is known as Herring's law of equal innervation (but see recent challenges to the universality of the law, King, 2011).

The Musculature of the Eyes

In humans, all eye movements are rotations of the eye (never linear motions or translations) and are accomplished by six extraocular muscles that operate in three antagonistic pairs. One pair, the medial and lateral rectus muscles, is located on either side of each eyeball and controls the horizontal orientation of the eye. A second pair, the superior and inferior rectus muscles, controls the vertical orientation of the eye and a third pair, the superior and inferior oblique muscles, controls rotations of the eye around the line-of-sight. Although most people are unaware of them, rotations of the eye about the line-of-sight are quite common, though usually less than 10° in amplitude.

Three Cranial Nerve Nuclei Control Tension in the Extraocular Muscles

The tension generated in each muscle is regulated by the activity of pools of alpha motor neurons located in the oculomotor brain stem. The pools of neurons regulating the superior rectus, inferior rectus, medial rectus, and inferior oblique muscles each lie within separate subdivisions of the oculomotor, or third cranial nerve, nucleus. Neurons innervating the superior oblique muscle lie within the trochlear, or fourth cranial nerve, nucleus. Neurons innervating the lateral rectus muscle lie within the abducens, or sixth cranial nerve, nucleus. Because these six pools are the only source of input to the extraocular muscles, they serve as a final common pathway through which all eye movement control must be implemented. Physiological studies of these neurons made while monkeys produced each of the five types of eye movements described above indicate that all of these motor neurons participate in the generation of all of the five classes of eye movements; there is no specialization among the alpha motor neurons for any particular class of movement. Engineering models of the eye and its muscles developed in the 1970s (largely by David Robinson and colleagues at Johns Hopkins University, USA; Robinson, 1981) indicate that each of these motor neurons must generate two types of muscle force to

accomplish any of the five classes of movements: a pulsatile burst of force produced during the movement, which regulates the instantaneous velocity with which the eye rotates, and a long-lasting increment or decrement in maintained force, which persists after the movement is complete. This maintained step in force holds the eye stationary by resisting the elastic forces of the muscles and connective tissues surrounding the eye. Forces that act to passively pull the eye back toward a straight ahead position. Physiological experiments have demonstrated that each motor neuron produces both of these two types of force. In summary then, the control circuits associated with gaze-stabilizing and gaze-shifting movements all must activate the same set of alpha motor neurons and all of these circuits must produce signals, which regulate both the velocity and position of the eyes in a manner appropriate for that type of eye movement.

Gaze-Stabilization Movements

Gaze-stabilization movements achieve image stabilization when the head rotates in space by rotating the eyes at a velocity equal to that of the head but, in an exactly opposite direction. Gaze stabilization thus requires very precise information about the speed and direction of head rotation across a broad range of head speeds. At high speeds of head rotation the vestibulo-ocular system obtains information from the semicircular canals of the inner ear, which accurately encodes the velocity of head rotation. However, as the velocity of head rotation decreases, the vestibular system begins to underestimate velocity. At low speeds, the optokinetic system obtains information about the rate at which the whole visual field slides across the retina, information which accurately encodes the velocity of head rotation. In this system, as the velocity of head rotation increases head velocity is underestimated. Thus either system working alone could not fully compensate for all movements of the head and body, but working together these two systems can provide an accurate estimate of head velocity that can be used by the oculomotor control circuitry to counterrotate the eyes in the head across a broad range of head speeds. Of course, regardless of the speed of eye rotation, as the eyes move toward far eccentric positions in the orbit, it eventually becomes impossible for the eyes to move any farther. The gaze-stabilization systems respond to this challenge by very quickly moving the eyes in the opposite direction; this gives rise to a repetitive pattern of quick reset movements and slow stabilization phases usually called nystagmus.

Vestibulo-Ocular Response

In the vestibulo-ocular system (often called the vestibulo-ocular reflex (VOR)) the rotational velocity of the head is transduced directly by the semicircular canals of the inner ear (even in total darkness) and enters the brain via the vestibular nucleus. Robinson and colleagues recognized that because this signal already encodes the velocity of head rotation, in order to compute the desired direction and velocity for a gaze-stabilization movement it would only be necessary for the brain to take the inverse of this signal. Recalling that all oculomotor alpha motor neurons produce both a pulsatile burst of force that regulates the velocity of the eye movement and a long-lasting steplike increment or decrement in maintained force that holds the eye stationary, Robinson proposed that the vestibular signal could be channeled directly to the alpha motor neurons to produce the pulsatile burst of force. He then went on to suggest that changes to the long-lasting step in force required after each eye rotation could be computed from this pulse, or velocity, signal by the mathematical operation of integration. In the 1980s the lesion of a discrete brain area, the nucleus prepositus hypoglossi, was shown to eliminate only the long-lasting force change from the motor neurons without affecting eye velocity during movements, suggesting that the nucleus prepositus hypoglossi is a neural integrator employed by the oculomotor system (Leigh and Zee, 1991).

Optokinetic Response

In the optokinetic response (often called optokinetic nystagmus (OKN)) head velocity is computed based on the global motion of the retinal image. This computation, determining the speed and direction of image motion, is performed in the pretectum and yields a signal that also specifies the rotational velocity of the eyes necessary to achieve image stabilization. This visually derived signal passes to the vestibular nucleus where it has been shown to combine with the vestibular signal used by the VOR to yield a neural estimate of head velocity that is accurate across the entire range of speeds for which gaze stabilization can be accomplished. This combined signal is then processed by the same circuitry that Robinson and his colleagues described for the vestibulo-ocular system. Gaze stabilization thus appears to involve two sensory systems that are combined and passed to a single control circuit that governs eye rotation.

Gaze-Shifting Movements

In some sense, gaze-shifting movements oppose gaze stabilization. While the VOR and OKN stabilize images on the retina to maximize visual acuity, gaze-shifting movements redirect the line-of-sight, temporarily reducing the acuity with which some or the entire visual world is perceived.

Saccades

The saccadic system, in order to achieve a precise gaze shift, must supply the alpha motor neurons with a command that controls the amplitude and the direction of the desired change in the line-of-sight. Current evidence indicates that this command can originate in either of two brain structures: the superior colliculus of the midbrain or the frontal eye fields of the neocortex (Sparks, 1986). Both of these structures contain laminar sheets of neurons that code all possible saccadic amplitudes and directions in a topographic maplike organization and both project to brain stem regions that supply control signals to the oculomotor neural integrators and the motor neurons described above. Activation of neurons in these collicular and cortical maps has been shown to precede the onset of saccadic eye movements by about 30 ms. One group of theories proposes that these cortical and collicular signals

govern a brain stem feedback loop (incorporating the neural integrator), which accelerates the eye to a high velocity and keeps the eye in motion until the desired eye movement is complete while other theories make similar predictions but place this feedback loop outside the brain stem. In either case, it seems clear that the superior colliculus and frontal eye fields are important sources for these signals because if both of these structures are removed, no further saccades are possible. The superior colliculus and frontal eye fields, in turn, receive input from many areas within the visual and parietal cortices, the basal ganglia, and brain structures involved in audition and somatosensation. These areas are presumed to participate in the processes that must precede the decision to make a saccade, processes like attention and target selection.

Smooth Pursuit

In the smooth pursuit system, signals carrying information about target motion are extracted by motion processing areas in the visual cortex and then passed to the dorso-lateral pontine nucleus of the brain stem. There, neurons have been identified, which code either the direction and velocity of pursuit eye movements, the direction and velocity of visual target motion, or both. These signals are passed to the cerebellum where neurons have been shown to encode specifically the velocity of pursuit eye movements. These neurons, in turn, make connections with cells known to be upstream of the nucleus prepositus hypoglossi (the oculomotor integrator described above). As in the other oculomotor systems, the brain stem integrator appears to compute the long-term holding force from this signal and then to pass the sum of these signals to the motor neurons.

Vergence

A number of different cues are used by primates to determine the distance to a visual stimulus and from this information to compute the convergence angle necessary to fixate a target. The relative positions of a stimulus falling on the two retinas (the binocular disparity of a stimulus) can be used to compute how much additional convergence or divergence is required to cause a stimulus to fall on the same position in each retina. The state of the lens in the eye can also be used to determine the distance to objects both in and out of focus and thus to compute the required vergence angle. For that matter, even perspective cues can be used to compute a desired vergence angle. In any case, all of these cues are used to activate brain stem circuitry, which appears to be very similar to the brain stem circuitry employed by the saccadic system. This brain stem circuit appears to generate a vergence velocity command similar to the saccadic velocity command, which is in turn integrated and passed on to the alpha motor neurons. Of course, unlike the commands for versional movements, in this case each eye receives a very different command for both velocity and holding force.

Summary

While many important questions remain the focus of active research, the oculomotor system is a comparatively well-understood set of neural mechanisms that serves as an excellent model for understanding movement control in general.

Abstract

The primary characteristics of eye movements (fixations, saccades, and regressions) during reading are described. Much of the emphasis is on skilled reading, but the eye movement characteristics of beginning readers and dyslexic readers are also discussed. Research findings on the following topics are also discussed: (1) the size of the perceptual span (or area of effective vision) during a fixation in reading, (2) integration of information across eye fixations in reading, (3) eye movement control – where to fixate next, and (4) eye movement control – when to move the eyes.

The primary characteristics of eye movements (fixations, saccades, and regressions) during reading are described. Much of the emphasis is on skilled reading, but the eye movement characteristics of beginning readers and dyslexic readers are also discussed. Research findings on the following topics are also discussed: (1) the size of the perceptual span (or area of effective vision) during a fixation in reading, (2) integration of information across eye fixations in reading, (3) eye movement control – where to fixate next, and (4) eye movement control – when to move the eyes.

Reading is arguably the most important skill that human beings acquire during their school years. An integral part of the reading process, both for beginning readers and for skilled readers, is the eye movements that occur when we comprehend text. In this article, some basic facts about eye movements during reading are discussed. Developmental changes in eye movements are also discussed, as are the following topics: the perceptual span (or span of effective vision), the integration of information across fixations, and the control of eye movements.

Basic Facts about Eye Movements during Reading

Although it seems as though we move our eyes smoothly across the text when we read, this is an illusion since our eyes make a series of movements (called *saccades*) that last about 20–35 ms. Between the saccades, our eyes are relatively still for about 200–250 ms (these periods when the eyes are stationary are called *fixations*). No information is obtained during saccades because the eyes are moving so quickly across the text; all new information is thus encoded during the fixations. Reading is therefore a bit like a slide show where each new slide (with a different view of the text) appears every quarter of a second or so. The saccade is typically 7–9 letter spaces and is not affected by the size of the print as long as it is not too small or too large. The appropriate metric to use when discussing eye movements therefore is letter spaces, and not visual angle (generally, 3–4 letter spaces are equivalent to 1 degree of visual angle). The other primary characteristic of eye movements is that about 10–15% of the time readers move their eyes back in the text (*regressions*) to look at material that has already been read.

Eye movements during reading are necessary because of acuity limitations in the visual system. With respect to the fixation point, any line of text can be divided into three regions: foveal, parafoveal, and peripheral. In the foveal region (extending 1 degree of visual angle to the left and right of fixation), acuity is sharpest and the letters can be easily resolved. In the parafoveal region (extending to 5 degrees of visual angle on either side of fixation) and the peripheral region (everything on the line beyond the parafoveal region), acuity drops off markedly so that our ability to identify letters is not very good even in the near parafovea. The purpose of eye movements in reading therefore is to place the fovea on that part of the text to be processed next. Whereas a majority of the words in a text are fixated during skilled reading, many words are skipped so that foveal processing of each word is not necessary. For example, content words are fixated about 85% of the time while function words are fixated about 35% of the time. Function words are fixated less frequently than content words because they are generally quite short and there is a relationship between word skipping and word length: as length increases, the probability of fixating increases; whereas 2–3 letter words are fixated less than 25% of the time, words that are 8 letters or longer are almost always fixated (and often fixated more than once).

When reading passages of text that are hard or unfamiliar, the eye movements of skilled readers are somewhat different from when they read text that is easy or familiar. As text difficulty increases, there are systematic effects on eye movements: fixation durations increase, saccade lengths decrease, and regression frequency increases. An important fact about eye movements in reading is that the ease or difficulty associated with understanding the text strongly influences the durations of fixations, the length of saccades, and the frequency of regressions.

It is important to note that the values presented above for fixation duration, saccade length, and regression frequency are averages and there is considerable variability in all of the measures. Thus, although the mean fixation duration is 200–250 ms and the mean saccade length is about 8 letter spaces, for individual readers these values might be somewhat higher or lower. Thus, the mean fixation duration for individual readers generally ranges between 200 ms and 300 ms and the average saccade length generally ranges from 6 to 10 letters. This between-reader variability (which also exists for regression frequency) is perhaps not as important as the fact that there is considerable within-reader variability. In other

words, although a reader's mean fixation duration might be 250 ms, the range of individual fixation durations can be from under 100 ms to over 500 ms within a passage of text. Likewise, the variability in saccade length can range from 1 letter (and sometimes even less than a letter) to over 15 letter spaces (though such long saccades typically follow regressions).

While fixation durations are typically examined when global aspects of reading are considered, when more detailed analyses involving individual target words are necessary, measures other than the mean fixation duration are usually examined. If readers always made one and only one fixation on a word then the fixation duration on the word would be the unit of processing. However, as noted above, words are sometimes fixated more than once, and sometimes they are skipped. Thus, using the mean fixation duration to infer the processing time for a word is inadequate because it underestimates the time the eyes are actually on the word; that is, a 200 ms fixation and a 150 ms fixation on the same word would yield a mean fixation duration of 175 ms, but the actual amount of time on the word would be 350 ms. Likewise, using only words that are fixated once (*single fixation duration*) is problematic because many words are skipped. Thus, the two most frequently used measures of processing time for a word are *first fixation duration* (the duration of the first fixation on a word independent of the total number of fixations) and *gaze duration* (the duration of all fixations on a word prior to an eye movement to another word).

Developmental Changes in Eye Movements

When children learn to read, they must learn to systemically move their eyes through text. Children in first grade typically fixate for 300–400 ms and only move their eyes a few characters. Thus, they fixate on virtually every word in the text. However, as reading skill develops, eye movements become more like those of skilled readers. By the time children are in fourth or fifth grade, the basic characteristics of their eye movements are like those of skilled readers. While their fixation durations and saccade lengths are similar to those of skilled readers, they do make more regressions than skilled readers. Children who experience severe difficulties learning to read (*dyslexic* readers) do not follow this systematic progression in the development of eye movement characteristics. Indeed, adult dyslexic readers make longer fixations, shorter saccades, and more regressions than skilled readers.

The Perceptual Span

How much information does a skilled reader acquire on each fixation and what is the size of the perceptual span (or area of effective vision) on each fixation? In order to investigate this question, the *eye-contingent display change* paradigm (McConkie and Rayner, 1975; Rayner, 1975; Rayner and Bertera, 1979) was developed. In this paradigm, a reader's eye movements are monitored (generally every millisecond) by a highly accurate eye-tracking system. The eyetracker is interfaced with a computer, which controls the display monitor from which the reader reads and changes in the text are made contingent on the location of the reader's eyes. Generally, the display changes are made during saccades and the reader is not aware of the changes.

There are three primary types of eye-contingent paradigms: the *moving window*, *foveal mask*, and *boundary* techniques. With the moving window technique, on each fixation a portion of the text around the fixation point is available to the reader. However, outside of this window, the text is replaced by other letters, or by Xs (see Figure 1). When the reader moves his or her eyes, the window moves with the eyes. Thus, wherever the reader looks, there is readable text within the window and altered text outside the window. The rationale with the technique is that when the window is as large as the region from which a reader can normally obtain information, reading will not differ from when there is no window present. The foveal mask technique is very similar to the moving window paradigm except that the text and replaced letters are reversed. Thus, wherever the reader looks, the letters around the fixation are replaced by Xs while outside of the mask area the text remains normal (see Figure 1). Finally, in the boundary technique, an invisible boundary location is specified in the text and when

Figure 1 Examples of the moving window (MW), foveal mask (FM), and boundary (B) paradigms. The first line shows a normal line of text with the fixation indicated by the +. The next two lines show an example of two successive fixations with a window of 15 letter spaces (7 to the left and 7 to the right of the fixation). The next two lines show an example of two successive fixations with a foveal mask of 7 letter spaces. The bottom two lines show an example of the boundary paradigm. The first of these lines shows a line of text prior to the display change; the second line shows the same line after the display change. When the readers' eyes cross the invisible boundary location (just after the last letter of the word *important*), the initially displayed word (*money*) is replaced by the target word (*skill*). The change occurs during the saccade and readers do not notice it.

the reader's eyes cross the boundary, an originally displayed word or letter string is replaced by a target word (see Figure 1). The amount of time that the reader looks at the target word is computed as a function of (1) the relationship between the initially displayed stimulus and the target word, and (2) the distance that the reader was from the target word prior to launching a saccade that crossed the boundary location.

For readers of English (and other alphabetic writing systems printed from left to right), the span extends from the beginning of the currently fixated word, or roughly 3–4 letter spaces to the left of fixation, to about 14–15 letter spaces to the right of fixation. The span is thus asymmetric – it extends further to the right of fixation than to the left of fixation. For readers of languages printed from right to left (such as Hebrew), the span is asymmetric but in the opposite direction from English so that it is larger left of fixation than right. While the span is asymmetric, it is the case that no useful information is acquired below the line of text that is currently being read as readers apparently focus their attention only on the line being fixated.

Although the perceptual span extends about 14–15 letter spaces to the right of fixation, the area from which words can be identified on a given fixation (the word identification span) generally does not exceed 7–8 letter spaces to the right of fixation. However, neither the perceptual span nor the word identification span is fixed as both can be modulated by word length. For example, if three short words occur in succession, readers are able to identify all of them. If the upcoming word is highly constrained by the context, readers acquire more information from that word than from unpredictable words, and if the fixated word is difficult to process, readers obtain less information from the upcoming word. Finally, the span is attention based and not due strictly to acuity factors (though they do have an influence) since if the letters get progressively larger away from fixation (to offset acuity limitations), the span is still about 14–15 letters to the right of fixation.

Orthography also influences the size of the perceptual span. Hebrew readers have a smaller span than English readers, and Japanese and Chinese readers have even smaller spans. Hebrew is a more densely packed language than English, and Japanese and Chinese are both more densely packed than Hebrew; densely packed refers to the fact that it takes more letters per sentence in English than Hebrew, for example. For Chinese readers, the span extends about one character to the left of fixation to 2–3 to the right. Finally, reading skill influences the size of the perceptual span. Beginning readers (at the end of second grade) have a smaller span than skilled readers and adult dyslexic readers have smaller spans than skilled readers.

Integration of Information across Eye Fixations

It is clear from research using both the moving window and the boundary technique that there is a *preview* benefit from having the word to the right of fixation available on an eye fixation, and that information obtained about the parafoveal word on fixation n is combined with information on fixation $n + 1$ to speed identification of the word when it is subsequently fixated. What kind of information is integrated across consecutive eye fixations in reading?

Experiments using the boundary paradigm described above have varied the orthographic, phonological, morphological, and semantic similarity between an initially displayed stimulus and a target word in attempts to determine the basis of the preview effect. A number of major findings have emerged from these studies. First, there is facilitation due to orthographic similarity as having a preview of *chest* facilitates the processing of *chart*. However, the facilitation is not strictly due to visual similarity because changing the case of letters from fixation to fixation (so that *ChArT* becomes *cHaRt* on the next) has little effect on reading behavior. Second, the facilitation is in part due to abstract letter codes associated with the first few letters of an unidentified parafoveal word; although there may be some facilitation from other parts of the word to the right of fixation, the bulk of the preview effect is due to the beginning letters. The effect is not simply due to spatial proximity because there is facilitation from the beginning letters of words when readers are asked to read sentences from right to left, but with letters within words printed from left to right. Third, there is facilitation due to phonological similarity, since *beech* facilitates *beach* and *shoot* facilitates *chute*, with less facilitation in the latter than in the former case. Fourth, although morphological factors can influence fixation time on a word, they are not the source of the preview benefit in English. Finally, although somewhat controversial, it has generally been found that there is no facilitation for readers of English due to semantic similarity since *song* as the preview does not facilitate the processing of *tune*. It thus appears that orthographic (abstract letter) and phonological codes are the basis of the preview benefit and used in integrating information across fixations.

Eye Movement Control: Where to Fixate Next

There are two components to the issue of how eye movements are controlled during reading: (1) where to fixate next and (2) when to move the eyes. It appears that there are separate mechanisms involved in these decisions and they will accordingly be discussed separately.

Word length seems to be the primary determinant of where to fixate next in skilled reading. When length information about the upcoming word is not available, readers move their eyes a shorter distance than when such information is available. Also, the length of the word to the right of fixation strongly influences the size of the saccade. Furthermore, there is a *landing position* effect such that readers tend to fixate about halfway between the beginning and the middle of words. However, there is also a *launch site* effect such that where readers land in a word is strongly influenced by where the saccade came from. Thus, whereas the most frequent landing position is near the middle of the word, if the prior saccade was launched some distance (8–10 letters) from the target word then the landing position shifts to the left of center. Likewise, if the prior saccade was launched close (2–3 characters) to the beginning of the target word, the landing position shifts to the right of center. Given this, the optimal strategy would be to fixate near the middle of each successive word. However, since short words can often be identified when they are just to the right of fixation, they are often skipped. Factors such as these result in the landing position distribution being spread somewhat.

Eye Movement Control: When to Move the Eyes

What determines when we move our eyes? The amount of time a reader fixates on a word or segment of text reveals something about the cognitive processes associated with comprehending that word or segment. One reason for this is that information gets into the processing system very early in a fixation (thus leaving a lot of time for processes associated with word recognition and other necessary comprehension processes). Experiments using the foveal mask paradigm in which the onset of the mask is delayed following a saccade have demonstrated that reading proceeds quite normally if the reader has 50–60 ms to process the text prior to the onset of the mask. If the mask occurs earlier, reading is disrupted. Although readers typically acquire the visual information needed for reading during the first 50–60 ms of a fixation, they can extract information at other times during a fixation as needed.

There have been many demonstrations that various lexical, syntactic, and discourse factors influence fixation time on a word. In particular, all of the following variables influence fixation time on a word: (1) word frequency, (2) contextual constraint, (3) semantic relationships between words in a sentence, (4) anaphora and coreference, (5) lexical ambiguity, and (6) syntactic disambiguation. Thus, for example, readers look longer (the first fixation duration and gaze duration are both longer) at words that do not occur as frequently in the language than they look at more frequent words, and they look at words that are highly predictable for less time than they look at words that are not predictable from the preceding context. In essence, the amount of time that readers look at words is strongly influenced by the ease or difficulty associated with understanding that word. Other factors also influence how long readers look at words. When reading a sentence such as "While Mary was mending the sock fell off her lap" (referred to as garden-path sentences), readers fixate for a long time on *fell*. This is because they typically parse *the sock* as a direct object and then do not know what to do with *fell* when they get to it. Thus, they need to reanalyze the sentence. In this particular example, readers would not only fixate for a long time on the disambiguating word (*fell*), they would also make a regression back to the earlier part of the sentence where the misanalysis began.

In essence, the variability in fixation durations that was mentioned at the outset of this article is largely due to the ease or difficulty of processing the fixated words. Because the oculomotor system is apparently closely linked to the part of the brain responsible for processing language, eye movements are a very good way to study various questions related to language and comprehension. Some computational models of eye movements in reading (see Engbert et al., 2005; Reichle et al., 1998, 2009) have been developed that nicely capture many of the properties of skilled reading.

Abstract

Eyeblink conditioning is a classical conditioning procedure that has been used extensively to investigate the neural mechanisms underlying associative learning and memory. The cerebellum ipsilateral to the conditioned eye is essential for eyeblink conditioning. Conditional stimulus (CS) and unconditional stimulus (US) input arising from the pontine nuclei and inferior olive, respectively, converge upon the cerebellar cortex and deep nuclei. Combined input from the CS and US pathways during training trials induces synaptic plasticity in the cerebellar cortex and anterior interpositus nucleus. These two sites of synaptic plasticity constitute the memory necessary for the eyeblink conditioned response. A future direction for this research is to determine the cellular and molecular mechanisms underlying cerebellar learning.

Introduction

The ability to learn relationships between stimuli and events that often occur together is known as associative learning, a fundamental form of learning that is critical for adapting to our environment. Associative learning involving reflexive behaviors is particularly amenable to objective scientific research since reflexes are reliably elicited and can be measured quantitatively more easily than complex behaviors. Initial experimental demonstrations of associative learning of reflexive behaviors are credited to the Russian physiologist Ivan Pavlov, and his work with salivary conditioning in dogs provided the basis for classical conditioning research. In a typical classical (or 'Pavlovian') conditioning procedure, a stimulus that initially does not produce the response being measured (e.g., a ringing bell, termed the conditional stimulus, or CS) precedes and reliably signals the occurrence of a stimulus that elicits the response being measured (e.g., food, termed the unconditional stimulus, or US). With sufficient pairings of the CS and US, the CS comes to elicit conditional responses (CRs; e.g., salivation) that, in some cases, are similar in form to the reflexive unconditional response (UR; e.g., salivation) elicited by the US. Classical conditioning experiments allow for precise experimenter control of stimulus exposure, and the use of proper control procedures readily identifies nonassociative contributions to performance.

Behavioral Studies of Eyeblink Conditioning

Eyeblink conditioning was established as a conditioning procedure for humans in the 1920s (Cason, 1922). In eyeblink conditioning, repeated presentations of a tone or light CS paired with a US that elicits a blink reflex (mild shock or air puff to the eye) yields anticipatory CRs (conditioned eyelid closure) that typically peak (i.e., when the eyelid reaches maximum closure) near the onset time of the US. Though human eyeblink conditioning procedures were refined over subsequent decades (see Woodruff-Pak and Steinmetz, 2000), various shortcomings inherent with eyeblink conditioning in humans including the presence of voluntary blinks and short latency unconditioned startle responses to auditory CSs led to the development of a rabbit model of eyeblink conditioning.

Isidore Gormezano, Alan Wagner, and their colleagues modified the human eyeblink conditioning setup to make it suitable for rabbits. Animal studies are necessary for invasive neuroscience research, and rabbits in particular are well-suited for eyeblink conditioning studies since they show a high tolerance for restraint, display low spontaneous blink rates, and show virtually no alpha responses to CSs typically used in eyeblink conditioning (see Gormezano, 1966). In the initial studies, adult rabbits were restrained within a Plexiglas box and received 70–82 daily presentations of a 600 ms, 72 dB tone CS that preceded a 100 ms puff of air to the cornea (US). The CS and US ended simultaneously (an example of 'delay conditioning'), so the interval between the onset of the CS and the onset of the US within each trial was 500 ms. A potentiometer was used to identify either (1) movement of the external eyelid (Schneiderman et al., 1962), (2) movement of the nictitating membrane (tissue that moves laterally across the eye of rabbits; Gormezano et al., 1962), or eyeball retraction (Deaux and Gormezano, 1963), and responses that exceeded a fixed threshold (typically 1 mm of movement) were recorded. Classically conditioned rabbits in all three experiments showed a gradual increase in CRs over the course of the 8-day training period. Overall, the percentage of CRs in classically conditioned rabbits was minimal early in training (typically less than 10%), but by the end of training CR percentages were 70% or higher, with maximum conditioned eyelid or nictitating membrane closure (CR peaks) occurring at or near the onset of the US. In contrast, control groups receiving the CS only, the US only, or random presentations of the CS and US averaged 10% or fewer CRs over the course of training, thus demonstrating that the associative pairing of the CS and US in the classically conditioned groups was essential for producing robust CRs. Importantly, CS-alone presentations led to a gradual dissipation of CRs in subjects previously given paired CS–US training, a type of inhibitory learning termed 'extinction' by Pavlov. Through extensive subsequent research that characterized properties of the eyeblink response (CR and UR) and examined ranges of parameters (e.g., CS–US intervals, CS and US intensities) capable of supporting conditioning, a comprehensive behavioral analysis of rabbit eyeblink conditioning was provided (see

Gormezano et al., 1983). With appropriate methodological and parametric adjustments the basic properties of eyeblink conditioning in rabbits are observed in many other infrahuman species (e.g., mice and rats), and the underlying neural substrates initially identified in rabbits are highly conserved across species, including rodents and humans.

Identifying Brain Regions Essential for Eyeblink Conditioning

The pioneering behavioral work by Gormezano and others (see Wagner, 1969) using rabbit eyeblink conditioning provided a foundation for investigating the neurobiological mechanisms that underlie associative learning. Richard Thompson and colleagues recognized the advantages afforded by eyeblink conditioning and adopted it as a model system for identifying the most direct links possible between associative learning and memory storage.

Multiple neuroscience techniques and approaches were used by the Thompson laboratory to identify the 'engram' (the neural representation of learning and memory; Thompson, 1976). One way proposed to identify candidate structures was to record neuronal activity in a region of interest during acquisition of eyeblink conditioning; if a particular region is essential one would expect that learning-related changes in neuronal activity would be evident. Because the target response (CR) is a discrete, well-timed eyelid closure that emerges gradually over multiple trials, eyeblink conditioning allows for reliable identification of neuronal activity that corresponds to learning. Indeed, the pattern of neuronal activity in the hippocampus predicts and models the time course of the eyeblink CR in subjects trained in the standard delay eyeblink conditioning procedure but not in subjects receiving unpaired presentations of the CS and US (Berger et al., 1976; Berger and Thompson, 1978). However, removal of the hippocampus does not impair acquisition of delay eyeblink conditioning (Schmaltz and Theios, 1972; Solomon et al., 1983), suggesting that this structure is normally involved but not essential for eyeblink conditioning. In fact, CRs are observed in decerebrate preparations, suggesting that the critical site(s) is/are located in the hindbrain (Mauk and Thompson, 1987).

Converging evidence based on electrophysiological recording, electrical stimulation, lesion, and reversible inactivation indicates that the cerebellum is essential for eyeblink (eyelid or nictitating membrane) conditioning (Christian and Thompson, 2003; Freeman and Steinmetz, 2011). Briefly: (1) neurons in the cerebellum exhibit learning-related activity that precedes the CR, suggesting a causal mechanism (**Figure 1**), (2) electrical stimulation of specific cerebellar regions is sufficient to produce eyelid closure, and (3) cerebellar lesions abolish CRs while leaving the UR intact, demonstrating that the absence of the behavioral expression of learning does not simply reflect an inability to perform the target response (McCormick and Thompson, 1984). Recording, stimulation, and lesions of a relatively small region of the cerebellum – the anterior interpositus nucleus ipsilateral to the trained eye – are sufficient to produce these results. Perhaps the most compelling evidence suggesting that the memory (engram) is formed and stored in the cerebellum comes from reversible inactivation studies. Rabbits receiving infusions of muscimol – a gamma-aminobutyric acid (GABA) agonist that temporarily hyperpolarizes neurons – into the cerebellum prior to daily eyeblink conditioning sessions failed to show CRs throughout training (URs were unaffected; Krupa et al., 1993). Subsequent training without infusions revealed a gradual emergence of CRs that was identical to initial acquisition in subjects receiving infusions of saline (vehicle), indicating there was no carry-over

Figure 1 Examples of electrophysiological activity (spikes/s) recorded from the anterior interpositus nucleus and corresponding eyelid movement in well-trained rats during paired eyeblink conditioning training. The green line represents conditional stimulus (CS) onset and the red line represents unconditional stimulus (US) onset. Note the increase in activity after onset of the CS. Figure adapted from Freeman, J.H., Steinmetz, A.B., 2011. Neural circuitry and plasticity mechanisms underlying delay eyeblink conditioning. Learning and Memory 18, 666–677.

or 'savings' from prior CS–US training. In contrast, muscimol infusions into sites efferent to the cerebellum that are involved (directly or indirectly) in control of blink-related movement (contralateral red nucleus; cranial motor neurons) blocked CR expression but had no lingering effects on postinfusion CRs. That is, CRs in these subjects were at asymptotic levels at the start of subsequent training with no infusions, indicating that substantial learning had occurred during inactivation sessions (Krupa et al., 1993, 1996). Similar findings were reported using different reversible inactivation techniques (Chapman et al., 1990; Clark et al., 1992; Clark and Lavond, 1993). Additionally, reversible inactivation of the cerebellum shortly *after* daily eyeblink conditioning sessions blocks retention of CRs, presumably resulting from disruption of memory consolidation (Attwell et al., 2002; Cooke et al., 2004). These findings indicate that the memory underlying eyeblink conditioning is formed and stored in the cerebellum, and not in downstream targets of the cerebellum.

Mechanisms of Cerebellar Learning in Eyeblink Conditioning

Memory formation and storage results from experience-dependent changes ('plasticity') occurring within the cerebellar cortex and anterior interpositus nucleus. Genetic manipulations provide an opportunity to explore how noninvasive disruption of potentially important mechanisms affects eyeblink conditioning. Genetically modified mice lacking specific receptor subtypes (Aiba et al., 1994; Kishimoto et al., 2002) or glial cell proteins (Shibuki et al., 1996) highly expressed in the cerebellar cortex are impaired in delay eyeblink conditioning and show impaired long-term depression (LTD) in the cerebellar cortex. LTD is demonstrated using *in vitro* electrophysiology and refers to persistent decreases in synaptic strength at parallel fiber-Purkinje cell synapses (as evidenced by depressed Purkinje cell activity) brought about by repeated, simultaneous stimulation of two distinct cerebellar afferents (Ito et al., 1982) shown to transmit CS and US information necessary for eyeblink conditioning (see Section Conditioned and Unconditioned Stimulus Input Circuitry, below). Purkinje cell axons form the entire output of the cerebellar cortex, projecting primarily to cerebellar deep nuclei. Furthermore, Purkinje cells produce action potentials at high frequencies under baseline conditions and form inhibitory synapses on their targets. Therefore, a depression of Purkinje cell firing (as in LTD) results in a 'release' of deep nuclear (e.g., anterior interpositus) neurons from chronic Purkinje cell inhibition. A model of cerebellar associative learning derived from a variety of techniques, including reversible inactivation and computer simulations proposes that LTD at parallel fiber-Purkinje cell synapses during the latter part of the CS in well-trained subjects produces a transient pause in Purkinje cell firing that 'disinhibits' cerebellar deep nuclei (Medina et al., 2000). According to this model, the learning-related cerebellar cortical plasticity permits additional plasticity – long-term potentiation (LTP) in cerebellar deep nuclei (Racine et al., 1986) – resulting in robust activity in deep nuclear neurons, thus producing the target response (e.g., eyeblink CR).

Consistent with the aforementioned model, electrophysiological recordings of Purkinje cell activity during eyeblink conditioning in well-trained subjects show a pattern of decreased firing during the latter portion of the CS (Hesslow and Ivarsson, 1994; Green and Steinmetz, 2005; Jirenhed et al., 2007), a period that coincides with the CR. This pattern of Purkinje cell activity is not observed early in training (Jirenhed et al., 2007), suggesting that the decreased activity during the CS in well-trained subjects represents LTD-like learning-related plasticity. Plasticity in the cerebellar cortex is essential for appropriate timing of the CR, and blocking Purkinje cell output in well-trained subjects leads to early onset, poorly timed CRs (Garcia and Mauk, 1998). Ohyama et al. (2006) used pharmacological manipulations as well as electrical stimulation of cerebellar afferents to demonstrate that these poorly timed CRs reflect plasticity in cerebellar deep nuclei and not in downstream targets (i.e., red nucleus). CRs were associative in nature and did not generalize to auditory cues (e.g., white noise) that had no prior history with the US. The associative and input-specific nature of these poorly timed CRs is consistent with an LTP-like mechanism in cerebellar deep nuclei underlying eyeblink conditioning. Additional indirect evidence for LTD-like mechanisms in the cerebellar cortex and LTP-like mechanisms in the cerebellar deep nuclei underlying eyeblink conditioning comes from electron microscopy studies. Specifically, reductions in excitatory parallel fiber-Purkine cell synapses (Connor et al., 2009) and increases in excitatory synapses per neuron in anterior interpositus nuclei (Kleim et al., 2002) have been reported in subjects receiving paired CS–US training relative to controls.

Although there is compelling evidence for LTD-like and LTP-like mechanisms in the cerebellum underlying eyeblink conditioning, alternatives must be considered. For one, cerebellar LTD and LTP have been demonstrated *in vitro* but have not been verified *in vivo* during eyeblink conditioning. Furthermore, some mutant mice that show impaired cerebellar cortical LTD are unimpaired in delay eyeblink conditioning (Schonewille et al., 2011). Additionally, delay eyeblink conditioning can proceed – albeit slowly – following global loss of Purkinje cells (Chen et al., 1996; Nolan and Freeman, 2006), indicating that cerebellar cortical LTD-like mechanisms may be normally involved but are not essential for eyeblink conditioning. Multiple plasticity mechanisms – in addition to plasticity at the level of the synapse – at different points throughout the essential circuitry are likely involved in the formation and storage of memory (see Hansel et al., 2001). It is important to note that these proposed mechanisms do not apply solely to eyeblink conditioning. The neural substrates and mechanisms underlying eyeblink conditioning are believed to underlie many other forms of cerebellar-dependent learning as well.

Conditioned and Unconditioned Stimulus Input Circuitry

Neural signals transmitting CS and US information converge upon the cerebellum to establish plasticity essential for eyeblink conditioning. CS information is conveyed to the

cerebellum from the pontine nuclei contralateral to the conditioned eye via the middle cerebellar peduncle. Mossy fibers from the pontine nuclei synapse with (1) granule cells in the cerebellar cortex (granule cell axons – 'parallel fibers' – make synaptic contacts with many Purkinje cells) and (2) cerebellar deep nuclear neurons (Shinoda et al., 1992; Mihailoff, 1993). Lesions of the middle cerebellar peduncle abolish learning with auditory, visual, or tactile CSs (Lewis et al., 1987), and electrical stimulation of the pontine nuclei or the middle cerebellar peduncle serves as highly effective CSs when forward paired with a peripheral US (Steinmetz et al., 1986). Electrical stimulation of lateral pontine nuclei produces robust CRs that are timed similar to CRs using peripheral CSs (Steinmetz, 1990), CRs gradually diminish in subjects trained with electrical stimulation as a CS following removal of the peripheral US (extinction), and lesions of the interpositus nucleus abolish CRs using stimulation of pontine nuclei or middle cerebellar peduncle as a CS (Steinmetz et al., 1987). These findings provide evidence that electrical stimulation of mossy fibers mimics the effects of peripheral CSs typically used for eyeblink conditioning. One concern with electrical stimulation is that it can produce axon potentials traveling back toward, rather than away from, the cell body (antidromic activation). However, eyeblink conditioning proceeds using middle cerebellar peduncle stimulation as a CS while upstream portions of the middle cerebellar peduncle (closer to the pontine cell bodies) are simultaneously inactivated (Hesslow et al., 1999).

CS information from different sensory modalities is transmitted to pontine nuclei through different pathways. Since most eyeblink conditioning studies use auditory CSs, the auditory CS pathway to the pontine nuclei will be the focus here (for a review of visual and somatosensory CS pathways, see Freeman and Steinmetz, 2011). Steinmetz et al. (1987) identified a projection from the cochlear nuclei to the lateral pontine nuclei and found that lesions of the lateral pontine nuclei prevented CRs when a tone, but not a light, was used as a CS. Subsequent studies have shown that the inferior colliculus and the medial auditory thalamus also provide auditory CS input that is necessary for eyeblink conditioning. The inferior colliculus provides auditory input to the medial auditory thalamus (Campolattaro et al., 2007), and lesions of the inferior colliculus impair eyeblink conditioning (Freeman et al., 2007). Lesions of the medial auditory thalamus prevent CRs to a tone CS but leave conditioning using a light CS unaffected (Halverson and Freeman, 2006). Furthermore, electrical stimulation of the medial auditory thalamus as a CS produces robust conditioning when forward paired (but not when unpaired) with a peripheral US (Campolattaro et al., 2007). Medial auditory thalamic nuclei send an ipsilateral projection to the pontine nuclei (Campolattaro et al., 2007), and this projection appears to be a necessary part of the auditory CS pathway since CRs produced from medial auditory thalamic stimulation are severely impaired by reversible inactivation of the lateral pontine nuclei (Halverson and Freeman, 2010). In summary, the auditory CS pathway includes separate projections from auditory nuclei (e.g., cochlear nuclei and the inferior colliculus) to the medial auditory thalamus contralateral to the conditioned eye, a direct projection from the medial auditory thalamus to the lateral pontine nuclei, and mossy fiber projections emerging from pontine nuclei to the cerebellar cortex and cerebellar deep nuclei (**Figure 2**).

Approaches similar to those used to identify the CS pathway have been used successfully in identifying the US pathway. The inferior olive receives inputs from sensory areas transmitting information from the cornea and face (e.g., trigeminal nerve) and US information is sent from the inferior olive to Purkinje cells in the cerebellar cortex (as climbing fibers) and to cerebellar deep nuclear cells (Shinoda et al., 2000; Sugihara et al., 2001). Electrical stimulation of the dorsal accessory inferior olive serves as an effective US when paired with a peripheral CS under appropriate parametric conditions and CR acquisition rates generated from this protocol are similar to acquisition rates in subjects receiving a peripheral US (Mauk et al., 1986). Destruction of the cerebellar deep nuclei prevents CRs generated from CS-inferior olive stimulation, and unpaired presentations of the CS and inferior olive stimulation following acquisition produces extinction (Mauk et al., 1986). Additionally, lesions of the inferior olive in well-trained subjects lead to an elimination of CRs that is either (1) gradual, similar to the pattern of CR decrement observed with removal of a peripheral US (McCormick et al., 1985), or (2) immediate (Yeo et al., 1986), closer to effects seen with lesions or inactivation of the interpositus nucleus. Though the basis for the differences in the time course of postlesion CR loss is unclear, these findings provide evidence that the inferior olive transmits US information to the cerebellum essential for eyeblink conditioning.

Cerebellar Feedback to the CS and US Pathways

The CS and US pathways receive feedback projections from the cerebellum. An inhibitory projection from the cerebellar deep nuclei to the inferior olive has been identified (Bengsston and Hesslow, 2006), and neuronal activity in the dorsal accessory inferior olive decreases during the US period over the course of acquisition of eyeblink conditioning (Sears and Steinmetz, 1991). This decreased activity in well-trained subjects is

Figure 2 Hypothesized auditory conditional stimulus pathway for eyeblink conditioning. There are inputs into the medial auditory thalamic nuclei (MATN) from the cochlear nucleus (CN), inferior colliculus (IC), and other auditory brainstem nuclei (superior olive – SO – and nucleus of the lateral lemniscus – LL). Input is then projected to the lateral pontine nuclei (LPN), which projects to the cerebellar cortex (CTX) and anterior interpositus nucleus (AIN). Hypothesized feedback projections from the AIN to the LPN and MATN are also shown (blue dashed lines). Figure adapted from Freeman, J.H., Steinmetz, A.B., 2011. Neural circuitry and plasticity mechanisms underlying delay eyeblink conditioning. Learning and Memory 18, 666–677.

evident in CS–US, but not in US-alone trials, suggesting that output from the deep nuclei related to CR generation is the primary cause. Inhibitory feedback from the deep nuclei to the inferior olive prevents learning about redundant or otherwise irrelevant stimuli (see Kim et al. (1998) for a role in the 'blocking' effect). A model of cerebellar function proposes that inhibitory, CR-related feedback from cerebellar deep nuclei is critical in maintaining learning-related plasticity by helping to provide an 'equilibrium' level of activity in the cerebellar cortex (Mauk and Donegan, 1997). Consistent with predictions from this model, blocking the influence of inhibitory feedback by infusing a GABA antagonist (picrotoxin) into the inferior olive prevents extinction during CS-alone presentations in well-trained subjects (Medina et al., 2002).

Cerebellar feedback identified upon the CS pathway, in contrast, is excitatory and may serve to strengthen CS input to the cerebellum. Projections to lateral pontine nuclei from the cerebellar deep nuclei have been identified (Steinmetz and Sengelaub, 1992; see **Figure 2**), and learning-related neuronal activity evident in the pontine nuclei in well-trained subjects is eliminated following inactivation of cerebellar deep nuclei (Clark et al., 1997; Bao et al., 2000). This pontine neuronal activity is not abolished by inactivation of the motor nuclei that control the blink response (Clark et al., 1997), suggesting that the pattern of pontine neuronal activity in well-trained subjects does not simply reflect performance of the CR. Halverson et al. (2010) identified projections from cerebellar deep nuclei to the medial auditory thalamus and recorded neuronal activity in the anterior interpositus nucleus and medial auditory thalamus simultaneously during acquisition of eyeblink conditioning. Robust, learning-related increases in neuronal activity emerged in the interpositus nucleus earlier than in the medial auditory thalamus across training sessions, and within trials, learning-related increases in interpositus activity preceded the CR while learning-related medial auditory thalamic activity typically emerged after CR onset. These findings suggest that cerebellar feedback may be driving learning-related activity in the medial auditory thalamus (**Figure 3**).

Conclusions and Future Directions

Eyeblink conditioning is perhaps the most suitable model system for identifying neural mechanisms underlying associative learning and memory. The discrete, robust target response is easily established in a number of species and across the lifespan. Although the essential neural circuitry is well-defined (see **Figure 4**), there are many issues that require further investigation. For one, it is still unknown how cerebellar feedback on CS and US pathways influences acquisition and retention of eyeblink conditioning. The availability of increasingly sophisticated neuroscience techniques (e.g., optogenetics) offers unique opportunities to explore not only dynamic interactions between the cerebellum and its inputs, but also plasticity mechanisms within the cerebellar cortex and deep nuclei. Plasticity mechanisms have been hypothesized, but the cellular and molecular mechanisms underlying learning-related plasticity throughout the essential cerebellum–brainstem circuitry require further examination. Related to these potential mechanisms is the relatively unknown role of cerebellar cortical interneurons. Recent characterization of *in vivo* firing profiles of identified

Figure 3 Hypothesized role of medial auditory thalamic plasticity in eyeblink conditioning. Learning is initiated by conditional stimulus-activated parallel fibers that arrive at Purkinje cells nearly simultaneously with climbing fiber input (window). No learning-related plasticity is evident in the interpositus nucleus (IPN) or medial auditory thalamic nuclei (MATN) during the initial training trials (*left*). Learning is potentiated by an increase (relative to initial training) in parallel fiber activity that occurs nearly simultaneously with climbing fiber input (window) and mossy fiber activity in the IPN. Learning-related plasticity is evident in IPN and MATN during later stages of learning (*right*). An increase in learning-related excitatory cerebellar feedback to the MATN (blue dotted line) may, in turn, increase the MATN output to the LPN and subsequently to the cerebellum to further facilitate learning. Figure adapted from Freeman, J.H., Steinmetz, A.B., 2011. Neural circuitry and plasticity mechanisms underlying delay eyeblink conditioning. Learning and Memory 18, 666–677.

Figure 4 A simplified diagram of the neural circuitry underlying eyeblink conditioning. The cerebellar anterior interpositus nucleus (AIN) and Purkinje cells (Pc) in the cerebellar cortex receive convergent input from the conditioned stimulus (CS, green) and unconditioned stimulus (US, red) neural pathways. The CS pathway includes subcortical sensory nuclei (SN) that include the medial auditory thalamus for auditory conditioning, pontine nuclei (PN), mossy fiber (mf) projection to the AIN and cortical granule cells (Gc), and the parallel fiber (pf) projections to Purkinje cells. The US pathway includes the trigeminal nucleus (TN), dorsal accessory division of the inferior olive (IO), and the climbing fiber (cf) projection to the AIN and Pc. The output pathway for performance of the conditioned blink response (orange) includes the AIN projection to the red nucleus (RN) and its projection to facial motor nucleus (FN) which causes eyelid closure. Feedback projections from the AIN to the PN, SN, and IO regulate CS and US input to facilitate acquisition and maintain plasticity within the cerebellum. Inhibitory synapses are depicted by a minus sign. All other synapses are excitatory. Figure adapted from Freeman, J.H., Steinmetz, A.B., 2011. Neural circuitry and plasticity mechanisms underlying delay eyeblink conditioning. Learning and Memory 18, 666–677.

interneurons (Ruigrok et al., 2011) may lead to a greater understanding of how these cortical cells influence eyeblink conditioning. The study of eyeblink conditioning has made tremendous contributions to our understanding of the neural bases of learning and memory and promises to remain an exciting area of investigation for years to come.

Abstract

Eyewitnesses have always played a fundamental role in the legal process. However, eyewitness evidence is not always as reliable or as accurate as one might hope, given the weight that decision makers often ascribe to it. In this article, we review some of the many factors that can determine the reliability of witness testimony, including factors that are, and those that are not, within the control of investigative and judicial processes. In doing so, we consider how policies might assist in ensuring that witness testimony can play the most effective and informative role in the legal process as possible.

Eyewitness testimony refers to the descriptions that bystanders or victims give to investigators, or in the courtroom, to describe what they can recall about the incidents under investigation. Since antiquity, eyewitnesses' testimony has overwhelmingly constituted the main basis for courts' and juries' decisions to convict or to acquit. Even today, many court verdicts are based almost exclusively on evidence provided by eyewitnesses. This is true even when other available case evidence clearly contradicts the eyewitnesses' reports and, importantly by extension, even when the witnesses are factually incorrect. The severity of this situation is epitomized by data from the Innocence Project, a public policy organization based in the USA. Using DNA testing, more than 300 individuals have been found to be wrongfully convicted, most commonly of murder or rape, and have consequently been exonerated. It is important to consider that these cases undoubtedly represent only a fraction of the true number of wrongful convictions, not least because in many cases forensic trace evidence was never, or is no longer, available to be DNA tested. More importantly, of these 300-plus cases, more than 75% were convicted at least in part on the basis of mistaken eyewitness identification (www.innocenceproject.org; Wells and Quinlivan, 2009). This rather worrisome situation can be linked to the fact that eyewitnesses' reports are typically perceived as more convincing than many other types of legal evidence, especially when those reports are expressed with high levels of confidence. In this article, we outline some of the most important factors – including confidence – that have been studied in the context of understanding what leads witnesses to be more versus less reliable.

Any given testimony is the product of a number of cognitive (intrapersonal) and social (interpersonal) processes. Perceptual and attentional processes are involved during the moments when individuals actually witness or are victims of a crime. Memory processes are involved in encoding, storing, and later retrieving the details of what has been witnessed. Metacognitive processes are involved in witnesses' decisions whether to report specific details that they remember. And in each of these instances, the social context within which these processes occur also plays a vital role. In this article we only briefly cover, for the sake of completeness, the initial perceptual and attentional processes, with particular emphasis on a phenomenon termed the 'weapon focus effect.' We devote more space to the complex and highly debated issue of witnesses' susceptibility to giving inaccurate reports of events. In this regard, we discuss the repeated finding that witnesses' confidence in their memories is only poorly related to the accuracy of their reports, and we also consider the widely studied phenomenon of the misinformation effect. Research in this area shows us how readily witnesses' reports can be influenced by authority figures, and by other witnesses of an incident. We next turn to consider research that debates how best to gather useful information from witnesses, both in the context of investigative interviews, and in the context of identifying culprits in police lineup procedures. An examination of factors that affect judges' perceptions of the reliability and credibility of witnesses will represent the last part of this article.

Eyewitness Factors

Given the importance and the persuasiveness of eyewitness testimony, it is of utmost importance for witnesses' reports to be accurate and reliable. Unfortunately, as confirmed now by many hundreds of studies, the reliability of eyewitness reports depends on a countless number of variables, some of which can lead the testimonial evidence to be weak, and some of which can lead it to be factually inaccurate. These variables have traditionally been divided into two types: system variables and estimator variables.

System variables are those that can be controlled through the processes and procedures of eliciting witnesses' memory reports; for example, the amount of time that investigators invest in building rapport with the witnesses in advance of their formal interviews, or the instructions given to witnesses before they participate in a lineup identification procedure. We will discuss many such variables in further detail later in this article. Estimator variables, in contrast, are those that cannot be controlled, but that nevertheless play important roles in determining the reliability of the end product. For example, we are unable to control the age of the witnesses, or the amount of alcohol they had imbibed at the time the incident occurred. Other important estimator variables include the perceptual conditions under which the bystander witnessed the incident (e.g., the lighting conditions) and other attentional factors (e.g., the witness's level of concentration and distraction).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.51033-2

Among the most widely studied estimator variables is the presence of a weapon during the incident, which can lead to a perceptual effect known as 'weapon focus.' Weapon focus refers to the tendency of witnesses to pay particularly high levels of attention to weapons when one is present during a crime. This attention to the weapon, in turn, comes at the expense of attention paid to other elements of the scene. As a result, the presence of weapons has been shown to lead to a poorer ability of witnesses to describe a perpetrator's appearance and to identify the perpetrator at a later time (Fawcett et al., 2013). Among the multitude of studies on this phenomenon, many authors have argued that in fact the 'weapon focus' effect may have little to do with weapons per se. Instead, this effect may be related to how a weapon is perceived in its situational context. Pickel (1999), for instance, showed her participants different videos depicting a perpetrator with a gun. She found that participants who saw the armed perpetrator at a baseball field were subsequently far less able to describe him than those who saw him at a shooting range. Similarly, Mitchell et al. (1998) found a comparable 'weapon focus' effect among participants who saw a perpetrator holding a gun, as among different participants who saw a perpetrator holding a stick of celery. Together, these data suggest that it is the unusualness of a weapon, rather than the threat that it seems to pose, which attracts attention. What the 'weapon focus' effect illustrates well, though, is that the reliability of witnesses can be influenced quite easily by straightforward visual elements of the incident. With regard to estimator variables more broadly, even though these are factors that the justice system cannot control, empirical research can nonetheless help us to understand these factors as means to predicting and understanding the circumstances under which witnesses will be most reliable.

Confidence–Accuracy Relationship

We noted above that the confidence of a witness can greatly determine judges' assessments of the reliability of their testimony. Confidence, unlike the other factors we have outlined so far, can be considered both an estimator and a system variable. That is to say, whereas it is largely influenced by the circumstances under which an event was witnessed, it can also be shaped and molded by subsequent social and investigative processes. A major focus of research on witness confidence has been on the confidence–accuracy relationship; that is, the question of whether witnesses who demonstrate higher confidence for testimonies are more likely to be correct, compared to witnesses who demonstrate lower confidence.

A conviction nowadays widely held by eyewitness researchers is that the accuracy of people's memory reports and their confidence in those reports are only weakly related, with most empirically derived correlations ranging between 0 and around 0.3 – by convention a weak-to-moderate relationship at best (e.g., Bothwell et al., 1987). Recently, however, a conceptual shift in thinking has occurred, and a new consensus has started to emerge that confidence may constitute a somewhat better predictor of accuracy than had previously been assumed. Specifically, researchers have argued that the weak relationship often documented between accuracy and confidence stems in part from the narrow testing conditions that are employed to assess this relationship, and in part from inappropriate statistical methods used to assess this relationship. With regard to the former reason, experimental studies on eyewitness memory typically aim to create homogenous study and testing conditions for all participants; that is, all participants experience a to-be-remembered event under highly similar conditions. This homogeneity leads to minimal variability in participant–witnesses' memory performance, which is in contrast to the conditions that occur in real life where different witnesses might observe the same event from different perspectives and distances, with different amounts of exposure time, and so forth. When variability in viewing conditions is minimized, the correlation coefficients that are used to assess the confidence–accuracy relationship can be artificially reduced. Indeed, in studies in which highly variable encoding conditions were created, larger (and therefore more meaningful) confidence–accuracy correlations were observed (Lindsay et al., 1998).

With regard to the second reason, several recent investigations into the confidence–accuracy relationship have recruited alternative analytic approaches, in place of the correlation analysis that is conventionally used in this literature. One such approach is calibration (Juslin et al., 1996). Calibration statistics tell us about the probability, based upon obtained data, that a given memory report expressed with a given degree of confidence is accurate, as illustrated in **Figure 1**. By using the calibration approach, Neil Brewer and his colleagues have demonstrated that confidence judgments generally track the accuracy of memory reports rather more meaningfully than correlation analyses would suggest (Brewer, 2006). In the area of eyewitness identification, where this method is now increasingly applied, it has been shown that confidence judgments are a reasonably good marker of accuracy of

Figure 1 A calibration curve representing data from 1000 hypothetical eyewitnesses; the dotted line represents 'perfect' calibration of witnesses' confidence and accuracy. The hypothetical data illustrate the most common pattern of findings in this literature: the confidence–accuracy correlation for the data set is weak to moderate in magnitude ($r = 0.3$), yet the calibration curve shows that witnesses' confidence judgments generally track their accuracy quite well, with a degree of overconfidence observed.

identifications among people who actually pick a person from a lineup (so-called 'choosers'). However, this relationship is weaker and not meaningful for those who reject the lineup (nonchoosers) – a distinction that has also been obtained in studies that used the conventional correlation approach to analysis (Sporer et al., 1995).

In sum then, there is some evidence that the strength of the confidence–accuracy relationship has commonly been underestimated, and that at least in some conditions, confidence can be a fairly good index of accuracy. Nonetheless, we should note that, however, it is assessed, a perfect confidence–accuracy relationship could occur only if confidence judgments were based on exactly the same information that shapes the accuracy of a memory report. This, however, is certainly not the case: confidence is often determined by external factors that have no influence on memory performance. The most obvious example of such a situation is the case of postidentification feedback in eyewitness identification experiments. Confirmatory feedback received after the identification decision ('Good, you identified the suspect') generally elevates witnesses' confidence in the correctness of this decision, although it clearly cannot have any influence on the actual accuracy of the decision itself (Douglass and Steblay, 2006). Research has shown that confirmatory feedback can influence witnesses' confidence not only when it is provided verbally, but also when it is provided through nonverbal and paraverbal cues, for instance, through nods or shakes of the head, or voice intonation, which might not be intended or even consciously recognized by the investigator (Garrioch and Brimacombe, 2001). In cases such as these, confidence and memory accuracy are at least partly based on different types of information, which may cumulatively contribute to an imperfect confidence–accuracy relationship.

To summarize, there are a variety of situations in which confidence may become dissociated from accuracy. These situations arise whenever accuracy is determined by different factors than confidence. It has to be noted, though, that the abundance of examples of confidence–accuracy dissociations reported in the literature can be partly explained by methodological and statistical factors. In the recent studies that recruit more precise measures of the confidence–accuracy relationship, and those that avoid homogenizing witnesses' experiences, confidence tracks the accuracy of a memory report rather more meaningfully than has more usually been concluded. What is undisputed, though, is that the relationship between confidence and accuracy is both imperfect, and susceptible to influence.

The Effects of Misinformation

As well as it being relatively easy to influence witnesses' confidence in their memory reports, substantial evidence has now been amassed showing that the actual accuracy of these reports is also relatively easy to influence. That is to say, witnesses' reports and identifications can be manipulated and changed as a product of various suggestive procedures. In the 1970s, psychologist Elizabeth Loftus pioneered research into what has been called the *misinformation effect*, a term that refers to the distortion of people's beliefs about – and memories of – past experiences as a consequence of receiving erroneous information about those experiences ('postevent information').

Given the weight eyewitness reports have on jurors' decisions, tainted reports are undoubtedly consequential in legal proceedings. The misinformation effect is among the most robust effects in the legal psychology domain, and has been replicated and elucidated by generations of researchers the world over. Loftus' early work was influential in demonstrating the simplicity with which witnesses' memory reports could be altered, for example, simply through the use of minimally leading questions or through the incidental mentioning of incorrect details during questioning (e.g., Loftus, 1975). Hundreds of studies since have given us a deeper understanding of how postevent information works, under what conditions, and what the consequences might be. In particular, there has been considerable debate over the question of whether misinformation actually changes witnesses' memories, or whether it simply supplements the original memories, perhaps making them less easily accessed (e.g., McCloskey and Zaragoza, 1985). As well as having theoretical importance insofar as our understanding of human memory is concerned, the answer to this question is also of practical importance – if misinformation actually changes memories, then no interviewing practice would successfully retrieve the original memories. Even to date, there is no firm consensus on the answer to this question, and there has been considerable evidence for both sides. What is certainly clear, though, is that postevent information is sufficient to lead witnesses to confidently report details that are factually incorrect. Moreover, discriminating a correct from an incorrect witness report can be extremely difficult in practice. Recent studies have demonstrated that witnesses can be led to implicate an innocent person in a wrongdoing even when the witnesses know that their testimony will have negative consequences for the other person (Kaasa et al., 2013; Wade et al., 2010).

The question of exactly who is most prone to the effects of postevent information has been extensively studied and debated over the years. Validated scales have been created, and widely used, to understand both the individual and situational predictors of interrogative suggestibility (that is, individuals' susceptibility to suggestions; e.g., Gudjonsson, 1984). Among other applications, these scales have been used to demonstrate that interrogative suggestibility is increased when interviewers behave in a 'firm' rather than friendly manner (Baxter et al., 2006), and that a variety of demographic and personal characteristics of an interviewee – including young or old age, learning disabilities, and life adversity – can make individuals vulnerable in this sense (Clare and Gudjonsson, 1993; Drake, 2010). More recently, research with Chinese participants demonstrated, among other findings, that people who are more intelligent and have better working memory ability are somewhat more immune to the effects of misinformation than are their peers (Zhu et al., 2010). Frost et al. (2013) recently showed that specific combinations of individual difference factors can selectively enhance acceptance of misinformation at different temporal levels. They showed that people who scored highly on measures of compliance tended to be those who would accept misinformation immediately, whereas those who scored highly on measures of fantasy proneness were those for whom the misinformation had robust and lasting effects. In other words, susceptibility to misinformation might rely on the interactions of different traits that separately predict

the acceptance of, and the elaboration of, the suggested information.

Cowitness Misinformation

As illustrated by the above studies, the problem of misinformation in the legal process has typically been studied and discussed with a focus on postevent suggestions provided by investigators, or otherwise authoritative sources. But in recent years, many researchers have begun to explore the effects and consequences of misinformation that is provided by cowitnesses – that is, by other bystanders or victims who also observed the incident. Survey research shows us that in a large majority of cases in which a crime has been witnessed, there is in fact more than one witness. Furthermore, in a large majority of cases involving multiple witnesses, cowitnesses discuss with each other what they saw, prior to giving initial testimony (Paterson and Kemp, 2006). Researchers have expressed concern that these cowitnesses could perhaps influence each other's memory reports, and these researchers turned out to be quite justified in their concerns. There are now a considerable number of studies demonstrating that discussion between two or more cowitnesses can lead individuals to confidently report observing details that only their colleagues observed. This 'cowitness misinformation effect' seems to be robust, but is considerably more prevalent in cases where the cowitnesses have a preexisting friendship or romantic relationship (Hope et al., 2008), and in cases where one observer is perceived to be a 'better' witness than the other (French et al., 2011). The cowitness misinformation effect is of particular concern for legal and investigative processes. Whereas police officers, for example, can be rigorously trained to avoid using suggestive interview practices, little can be done to prevent witnesses from speaking to each other, especially prior to their first contact with investigators. There is some evidence, though, that explicitly encouraging witnesses not to report details that they only remember being told, not actually seeing, can mitigate the effects (Bodner et al., 2009).

Gathering Evidence from Witnesses

Given the overwhelming evidence that witnesses' testimonies are malleable and susceptible to external influence, an important question is what we might do to minimize the likelihood of obtaining unreliable testimonies. We consider this issue here within two broad contexts: First, we consider established interviewing techniques that have been proposed – and indeed applied – as 'best practice' for gathering information from witnesses. Second, we consider the procedures used for obtaining suspect-identification evidence, via the use of police 'lineups.'

Interviewing Techniques

Several specific interviewing techniques have been proposed by researchers to ensure the maximum informativeness of witnesses' reports (in terms of the amount of detail they report) while also maintaining their quality (in terms of the accuracy of that detail). Of those techniques, the Cognitive Interview is to date the most studied (Memon et al., 2010), and below we focus mainly on this approach, though it is worth noting that this approach shares many commonalities with other best-practice interviewing protocols (e.g., the National Institute of Child Health and Development's Investigative Interview Protocol; Orbach et al., 2000), and we outline these general commonalities first. Most recommended interviewing techniques share the same basic principles of good practice, which can be summarized in the following points (see, for example, the Memorandum of Good Practice published by the United Kingdom's Home Office (1992; see also subsequent extensions and variations, for example, Westcott and Jones, 1997; Ministry of Justice, 2011)). First, efforts should be taken to build rapport and trust with a witness before any direct interviewing about the incident in question takes place. This rapport building can put witnesses at ease, can reduce social pressure upon them, and has been shown in some studies to actually improve the quantity and quality of information they subsequently provide (Vallano and Schreiber Compo, 2011). Second, the interview should begin with an opportunity for the witness to provide a free and uninterrupted account of what happened. Third, following this account, if it is necessary to ask questions of the witness, then these questions should be as open-ended as possible so as not to lead the witness to give any implied or suggested response. One can proceed to ask closed questions only when the material provided using open questions is deemed insufficient, and when closed questions are asked, these should be carefully worded so as not to contain new and/or leading information. One element stressed in some of the interviewing techniques is to preface the interview with a clear statement of what is and what is not expected during the interview – often referred to as establishing 'ground rules' (Memon et al., 2010). For example, one important way to enhance the accuracy of the report is to clarify that the witness is allowed to say 'I do not know' in response to questions (Orbach et al., 2000). In general, research shows us that when police officers are trained to interview witnesses by following best-practice recommendations such as those we have described, they conduct better quality interviews as a result, and can elicit information from witnesses that is of greater investigative value (e.g., Pipe et al., 2008).

As we mentioned above, the Cognitive Interview is the investigative interviewing technique that has arguably received the most empirical scrutiny in the psychological literature. The technique, originally developed by psychologists Ed Geiselman and Ron Fisher in the 1980s (Geiselman et al., 1985) and since refined and augmented in further revisions, is specifically designed to maximize the amount of information that a witness can provide. The Cognitive Interview in its original format comprised four components that could be used to assist witnesses' recollections, each of which was conceived on the basis of psychological research on remembering. The first is known as mental reinstatement of context, and involves encouraging the witness to carefully visualize the incident in their mind's eye, and to bring to mind the sounds, smells, thoughts, and feelings that they had experienced at the time. During this exercise, witnesses might be encouraged to close their eyes, and recent research has shown that this too can enhance recollection (Vredeveldt and Penrod, 2013). The second component is termed 'report everything,' and involves

instructing the witness not to selectively edit their accounts on the basis of what they personally think is important, or what they think the investigator is looking for. Reporting everything is important not only because ostensibly trivial details can often turn out to be critical, but also because recalling these trivial details can sometimes trigger the recollection of other, less trivial details. The third and fourth Cognitive Interview components require recalling the incident in different ways – from different perspectives (trying to visualize the events from a different viewpoint than one's own) and in different orders (trying to recall in reverse order, or starting from the middle rather than from the beginning of the event). These latter stages have rather fallen out of favor in recent times, however, as studies show not only that police rarely use the techniques (Dando et al., 2008), but also that removing them from the protocol can speed up interviewing times without any meaningful loss of information reported, as illustrated in **Figure 2** (Dando et al., 2009).

Substantial research has validated the Cognitive Interview method. Dozens of studies conducted both in laboratory settings and in the field have shown that using the Cognitive Interview components substantially increases the amount of correct detail that witnesses recall, although a smaller concomitant increase in incorrect detail is also often obtained (Memon et al., 2010). In short, witnesses interviewed using the Cognitive Interview technique tend to give more complete and overall more accurate accounts. No wonder, then, that this approach is now formally used in police training in several countries including the United Kingdom, New Zealand, and Israel.

One serious practical issue is that even among these proven effective interviewing techniques, none can necessarily be administered immediately after an incident occurs; that is to say, due to limitations in police resources, it may often be several days or even weeks after a crime occurs before investigators are able to properly interview the witnesses. The problem then remains that during this interval, considerable amounts of useful information might be forgotten, and external sources might interfere with or add to witnesses' recollections. To obviate this problem, a new method has recently been proposed, labeled the 'Self-Administered Interview' (Gabbert et al., 2009), which has now been extensively tested in the field. The method is based upon the principles of the Cognitive Interview, but translated into a paper-based interview protocol that a witness completes independently at their earliest opportunity, in advance of a formal police interview that might take place at a later time. Gabbert et al. (2009) showed – as have several researchers since – that completing a Self-Administered Interview can reduce the extent of forgetting of incident-related information during a delay of around 1 week. Using this tool, therefore, represents one straightforward and effective way by which investigators might maintain the quality of witness evidence even in the face of difficult-resourcing problems. Nash et al. (2014) recently proposed that conducting remote interviews – without the physical copresence of the interviewer and witness – might be another possible solution to this delay problem in some instances. They argued that in some cases, such remote interviewing might circumvent some of the causes of delays. Nash et al.'s data supported the notion that conducting a remote interview sooner would lead to better recall than would conducting a face-to-face interview later; however, further empirical exploration of this modern technological solution is clearly needed. In general, it is clear that research can play a considerable role in finding and testing solutions to difficult and ingrained problems in investigative processes, which stand to improve the integrity and completeness of eyewitness evidence.

Lineups

Lineup procedures, referred to in some countries as 'identity parades,' are an example of a recognition task in which

Figure 2 Results from Dando, C.J., Wilcock, R., Milne, R., Henry, L. (2009. A modified cognitive interview procedure for frontline police investigators. Applied Cognitive Psychology 23, 698–716), in which 60 eyewitnesses were interviewed about a recent event using either a standard interview protocol (i.e., not involving the cognitive interview components), a cognitive interview, or a modified cognitive interview that omitted the change-order and change-perspective components. Error bars are 95% confidence intervals and mean interview durations are shown for each condition.

a witness has to decide whether a previously seen person is present among a selection of possible candidates. Lineups can be distinguished from 'showups,' in which a witness is presented with just one person and asked to decide whether this person is the perpetrator or not. Even though it is significantly more laborious to administer a lineup than a showup, the popularity of lineups is based on a general consensus that lineups are fairer procedures than are showups (Wells and Quinlivan, 2009).

Emerging from decades of studies on lineups, a number of guidelines have been proposed pertaining to how lineups should best be administered so as to obtain reliable identification decisions (e.g., Wells et al., 1998). Among other types of advice, these guidelines cover the instructions that should be given to witnesses prior to the procedure, the person who should administer the lineup, and the way by which the foils (that is, people who are known to be innocent) in the lineups should be chosen. There is a general consensus that the instructions given to a witness should be unbiased, that is, they should stress that a perpetrator may or may not be present in the lineup (Steblay, 1997). Studies show that providing biased instructions leads to a higher rate of both correct and incorrect identifications, which, therefore, means that such instructions increase the risk that an innocent suspect will be prosecuted. Researchers also agree that a person administering the lineup should not be aware of which lineup member is the suspect, so that the administrator could not deliberately or unwittingly influence a witness through nonverbal or verbal cues (Wright et al., 2010). Finally, it has been proposed that foils in a lineup should be chosen not based on similarity to the suspect but based on a witness's description of a perpetrator (Luus and Wells, 1991). One good reason for this rule is that if the foils are all chosen to look as similar as possible to the suspect, this might mean the witness's task is made unnecessarily difficult. So long as the foils and suspect all match the witness's description, however, there should be no unfair bias against the suspect, but the recognition cues by which the witness might make a confident identification will be preserved and made more salient. In other words, using a culprit-description strategy rather than a suspect-similarity strategy should improve the likelihood of identifying the perpetrator, without unfairly leading the witness to pick the suspect.

A very large number of research studies on lineups have been devoted to the issue of the format of presentation. Usually, there are two possible formats by which a lineup could be administered. In a simultaneous lineup, a suspect and all foils are presented at the same time, and a witness is asked to make a single decision: to either identify one member of the lineup as being the perpetrator, or to reject the lineup by saying that the perpetrator is not present. In a sequential lineup, a suspect and foils are instead presented one-by-one, and the witness is asked to decide for each presented person whether he or she is the perpetrator. The interest in these two formats of presentation was sparked by reports showing that sequential lineups lead witnesses to use more reliable decision-making processes than do simultaneous lineups (e.g., Lindsay and Wells, 1985). Specifically, it has been argued that sequential lineups prevent witnesses from using a relative judgment strategy, whereby the members of the lineup are compared to each other with the aim of determining, which looks most similar to the perpetrator. This relative judgment strategy is thought to underlie many false identifications, whereby the suspect looks like but is not in fact the perpetrator. Reports on the superiority of sequential lineups have been convincing enough to persuade some legal authorities to promote the sequential approach in their actual investigative proceedings. Nevertheless, similar to the discussion above regarding the confidence–accuracy correlation, some researchers have more recently suggested that the sequential superiority effect is actually an artifact of the statistical techniques used to examine the data. Using what they argue are more appropriate statistical techniques, Mickes et al. (2012) have shown evidence that the simultaneous procedure is, in fact, the better method for discriminating between the presence and absence of a perpetrator in a lineup. Despite the abundance of evidence thus far for preferring sequential lineups, arguments such as these will no doubt lead to considerable empirical and policy scrutiny in the years to come.

When considering lineup identification data, it is important to distinguish between the general propensity of a witness to select a person in a lineup, and the actual reliability of these decisions. The relevance of this distinction extends beyond the discussion on the sequential vs. simultaneous debate. Indeed, in a recent overview of the guidelines proposed to enhance reliability of lineup identifications, Clark (2012) argued that the best-practice guidelines outlined above, including unbiased instructions and the 'double blind' administrator rule, affect witnesses' *tendency* to identify somebody rather than the *reliability* of their identification decisions. In other words, various techniques can make witnesses less ready to identify someone in the lineup, and these techniques will, therefore, result in a lower rate of wrongful identifications but at the important cost that fewer correct identifications would also be made. Countering this argument, other authors pointed out that many of the correct identifications made under suggestive or otherwise inadequate lineup procedures might not be legitimate 'hits.' Rather, they might well include guesses and selections based upon external 'hints' (Newman and Loftus, 2012). These authors argue that we do not gain from increasing correct identifications for the wrong reasons. In short, there is clearly a degree of ambiguity regarding what kinds of identifications are desirable; that is, to what extent the 'ends justify the means.' This ambiguity is compounded by the difficulty of knowing in practice, when the perpetrator is not known, whether a witness's choice is actually based upon true recognition, rather than on unwanted influence.

Jurors' Appraisals of Witness Reliability

Whereas witnesses undoubtedly vary in their accuracy, it is the task of legal decision makers such as judges and juries to determine how much weight to ascribe to a given testimony. Whether a testimony or identification that is made by a witness will influence judges and jurors depends on the extent to which that witness is perceived to be reliable, that is, the extent to which he or she is judged to have an accurate recollection of the incident.

The accuracy of jurors' appraisals of witness reliability will depend partly on the accuracy of their beliefs concerning how

human memory works. For example, if jurors believe that postevent information would not affect the accuracy of a testimony – a belief starkly contrasting with experts' knowledge about eyewitness testimony – then the jurors' perception of the reliability of a given memory report may be severely distorted. A number of studies have, therefore, looked at how potential jurors' lay theories of memory match the expert consensus informed by empirical studies. A recent meta-analysis of these studies, conducted by Desmarais and Read (2011), suggests that in some respects potential jurors' beliefs match quite well what experts know about the reliability of testimonies, but that they clearly contrast with experts' knowledge in other respects. However, one issue that must be taken into account is that in the majority of studies on this topic, juror knowledge has been measured through respondents' ability to correctly answer multiple-choice questions on various eyewitness topics. The extent to which the ability to correctly answer such questions is an adequate index of 'knowledge,' and the extent to which this knowledge would be spontaneously applied by jurors in a real legal case, are disputable. As a result, one might conclude that the estimates of juror knowledge obtained in these studies are 'best-case scenarios,' and further research with different measures of knowledge would clearly be useful.

Besides the knowledge of factors that may affect the reliability of testimony, jurors' appraisals of testimony are also determined by the features of the testimony itself. One factor determining perceptions of reliability is the sheer amount of details provided in a testimony. Research shows that a testimony is often perceived to be more accurate when it contains more details, even if these details are trivial and of little relevance to the central issue about which the witness testifies (Bell and Loftus, 1988). Also, a large number of studies clearly indicate that perceived reliability is strongly affected by witnesses' declared confidence in their own testimony (e.g., Whitley and Greenberg, 1986). The more confidently the statement seems to be made, the more accurate and reliable it is perceived to be. As discussed in the section above concerning confidence–accuracy relationship, this strategy – although reasonable under many circumstances – could lead to misplaced reliance on witnesses whenever their confidence and accuracy have become dissociated.

With these findings in mind, it is worth noting that jurors do seem to appropriately balance the persuasiveness of the details provided in a testimony, and that of witnesses' confidence, against the persuasiveness of evidence from other sources. One major clue to the reliability and credibility of an eyewitness often lies in this congruency of evidence. When an eyewitness is contradicted even on a trivial detail, the assessed reliability of that eyewitness is starkly reduced (Wells and Leippe, 1981). Also, when a witness is proven wrong on a detail that was reported with high confidence, this witness's perceived reliability is undermined by a much greater extent than when a witness is proven wrong on a detail reported with low confidence (Tenney et al., 2007). Therefore, although confidence is often considered by judges and juries as an indicator of reliability, the apparent relationship between witnesses' confidence and accuracy on individual elements of their reports can also shape the appraisal of their testimony.

Conclusion

As we noted at the beginning of this article, law courts in many countries have always readily based their decisions on witness evidence, and this continues to be true today. This is most likely for three reasons. First, in many circumstances no other evidence is available. Second, variables that are capable of modifying witnesses' reports are so ubiquitous that discarding evidence that is potentially unreliable might lead to discarding most witnesses' reports. Finally, witness evidence is typically interpreted as being highly convincing, both by judges and by members of the jury. For these reasons, it remains highly important that investigators, judges, jurors, and policymakers all understand the circumstances under which witnesses are most likely to be reliable, and know the investigative procedures that can help us to maximize this accuracy. Such understanding will help us to ensure that witnesses play the most effective and informative role in the legal system as possible.

Face Perception Development During Early Childhood

Gudrun Schwarzer and Claudia Freitag, University of Giessen, Giessen, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article addresses the development of face processing during the first 4 years of life. Beginning with newborns' preference for faces we describe how and when infants begin to categorize and recognize different aspects of faces like gender, attractiveness, and familiarity. We also examine the extent to which young children rely on featural and configural information when they process faces. Further on we focus on the processing of social information in faces like emotional expressions and gaze direction. We finally provide evidence that experience plays a crucial role in the development of face expertise in infants and young children.

Introduction

Faces are highly complex visual stimuli. They simultaneously convey information regarding the identity of a person and a variety of social information, such as emotions or social intentions. Face identity refers to the relatively stable visual information in a face that comprises individual facial features, such as the eyes, nose, and mouth, as well as the configuration of these features. The emotions or intentions of a person, in contrast, correspond to rather dynamic or transient visual cues, including emotional expressions or eye gaze.

Despite the complexity, adults are experts at processing faces. They are remarkably accurate and fast at recognizing previously encountered people by their faces (Sergent, 1989). They can store and recognize hundreds of faces (Bahrick et al., 1975) and can quickly decode emotional expressions and direction of gaze. It is not surprising that extensive research has been carried out in an attempt to understand the developmental origin of such an impressive ability. In everyday life when young children interact with other people they have to process the variety of face information, which challenges their perceptual and cognitive abilities. Previous research suggests that both nature and nurture play a crucial role in the development of face processing (Park et al., 2009). For example, there is evidence that infants display an innate preference for faces. When offered different visual stimuli, newborns are especially attracted to faces, preferring faces to other patterns (e.g., Mondloch et al., 1999; Valenza et al., 1996). However, other studies have demonstrated that experience also plays a significant role in the development of face processing. Early experience with specific types of faces (faces of a specific species or race) leads to lasting advantages in the processing of those faces (e.g., Pascalis et al., 2002).

The aim of this article is to review the body of evidence on the nature of the face processing system during infancy and up to the first 3–4 years of life. We first comment on infants' early preference for faces. Then, we describe the development of two different processes, the categorization of faces as belonging to a specific category, e.g., attractiveness or gender, and the recognition of a certain face on an individual level. We also examine the extent to which young children rely on featural and configural information when they process faces. Then, we review the role of social face information, and finally, we conclude with the role of experience in children's face processing.

Preference for Faces

The human face is most likely the first social stimulus with which newborns interact. They not only attend to faces, but prefer to look at faces shortly after birth. Several studies showed that newborns looked longer at schematic stimuli with face-like arrangements than at stimuli with similar complexity but without face-like configurations (Frantz, 1961; Goren et al., 1975; Johnson et al., 1991; Maurer and Young, 1983; Mondloch et al., 1999; Simion et al., 1998a,b; Turati et al., 2002). A configuration of two small quadrates symbolizing the eyes arranged above a centered quadrate symbolizing the mouth, surrounded by a circle, seemed to be essential for evoking such a preference (Johnson and Morton, 1991). Newborns also prefer to look at photos of real faces when presented upright, compared to photos of faces presented inverted (180° rotation, see Figure 1), again indicating their preference for the face-like configuration of eyes above the mouth (Macchi Cassia et al., 2004). Di Giorgio et al. (2012) reported that newborns' preferences for faces were not restricted to human faces but also applied to nonhuman primate faces. During the first weeks of life, face preference seems to narrow toward real human faces compared to schematic faces. Face preference for schematic faces was less

Figure 1 Example of an upright and inverted face.

pronounced at the end of the first month and was no longer existent in 3- to 5-month-old infants (Johnson et al., 1991).

The mechanisms underlying early face preference are controversial. The dual mechanism theory of Morton and Johnson (1991) presumes that newborns have an innate mechanism that includes knowledge of face structures. Such a mechanism, termed CONSPEC, triggers the infant's attention to actively search for faces during the first months of life. The information gathered by CONSPEC is processed in the primitive subcortical brain structures. Beginning at approximately 2 months of age, a second independent mechanism of face processing, termed CONLEARN, develops and processes face information in cortical brain structures. Based on increasing experience with faces, CONLEARN enables the perception of individual differences between faces and the recognition of familiar faces.

In contrast to the dual mechanism theory, infant face preference has been explained by nonspecific perceptual constraints arising from the general properties of visual processing shortly after birth (Turati, 2004). Here, it is assumed that infants are sensitive to a specific stimulus configuration, termed up-down asymmetry and prefer to look at stimuli comprising more information in the upper half than in the lower half (see Figure 2, Simion et al., 2001). This visual configuration is considered to be typical and is most often provided in faces but is not unique to faces alone (Banks and Salapatek, 1981; Simion et al., 2003). In summary, both theories presume that newborns are prepared to orient to faces shortly after birth but they differ in how this early preference for faces is explained, i.e., due to an innate representation of faces or due to less specific attentional biases.

Categorization and Recognition of Faces

Not only do infants prefer to look at faces, they also begin to categorize faces according to attractiveness, gender, or emotional expression. Categorizing in general implies the existence of a prototype that reflects the average of different exemplars within one category (Quinn and Slater, 2003). A face prototype is characterized as the internal representation of an average face based on all of the individual faces that a person has processed

Figure 2 Non-face-like stimuli used to study infants' preference for up-down asymmetry. Simion, F., Macchi Cassia, V., Turati, C., Valenza, E., 2001. The origins of face perception: specific versus non-specific mechanisms. Infant and Child Development 10 (1–2), 59–65. Reproduced with permission.

so far (Valentine, 1991, see later). At the age of 3 months, infants are able to build face prototypes while before that age each face is stored separately with no reference to the internal representation of other faces (de Haan et al., 2001). The authors habituated 1- and 3-month-old infants to four faces and then tested them using a morphed face representing the average (the prototype) of all four faces. While those aged 3 months recognized the prototype, the 1-month-old infants did not. Thus, infants are able to form face categories at approximately 3 months of age due to their ability to build prototypes and their growing experience with faces.

The attractiveness of faces as classified by adults is a categorization that infants are sensitive to. By 6 months of age, infants prefer to look at attractive faces compared to faces classified as less attractive, independent of the ethnicity, gender, and age of the faces (Langlois et al., 1991). Such an early preference can be due to the fact that infant face prototypes resemble adult face prototypes, as infants mostly experience adult faces, and that attractive faces are almost identical to the face prototypes of the relevant gender in adults.

Another facial category that infants learn to discriminate is gender. The majority of 3-month-old infants tested in a preferential-looking paradigm preferred to look at female faces, compared to male faces (Quinn et al., 2002). The authors explained this result with the observation that many of the infants were raised by female caregivers, leading to greater levels of experience with female faces. This hypothesis was supported by the finding that infants raised by male caregivers preferred to look at male faces.

The ability to categorize emotional facial expressions arises at approximately 7 months of age (Nelson et al., 2006). At that age, infants begin to discriminate emotional expressions in faces of different ages and genders (Bornstein and Arterberry, 2003; Nelson, 2001), indicating that they are able to generalize emotional expressions across multiple exemplars of faces. Nelson et al. (2006) demonstrated that happiness was the first emotional expression that was recognized in different faces, followed by the expression of fear at the end of the first year. At the same time as infants begin to categorize emotional expressions they also become sensitive to the intensity of an emotional facial expression and are able to categorize mild and strong expressions of happiness and anger (Striano et al., 2002).

The skill needed to discriminate distinct emotional expressions within an identical face, which is more basic than that needed to categorize facial expressions, arises earlier, at approximately 3 months of age. Based on studies using a habituation paradigm, 3-month-old infants were able to discriminate between happiness and surprise within an identical face but not between happiness and sadness (Young-Browne et al., 1977). It seems that familiarity facilitates the discrimination of emotional expressions in young infants, as 3.5-month-old infants were able to discriminate between expressions of happiness and anger in their mothers' faces but not in unfamiliar female faces (Kahana-Kalman and Walker-Andrews, 2001). Some weeks later, at 4–5 months of age, infants seem to be able to discriminate between happiness, anger, and neutral expressions (La Barbera et al., 1976), as well as between sadness and fear within identical unfamiliar faces (Schwartz et al., 1985). Beyond the first year of life, infants and toddlers become more and more efficient at recognizing emotional expressions in different poses (Bruce et al., 2000) based on inner facial features only (Mondloch et al., 2003). Three year olds are almost error-free in recognizing basic emotions, with the highest accuracy in recognizing happiness (Strand et al., 2008), while the categorization of more complex emotional facial expressions, such as shame and abashment, were not achieved until the middle childhood years (Markham and Adams, 1992).

Familiarity of faces is another crucial category that infants have to learn, as it is essential for emotional binding and social communication to be able to discriminate between familiar and unfamiliar faces and to recognize personally familiar faces. It is not surprising that the caregiver's face is the first to be recognized by infants. At 2–36 h after birth, newborns' sucking responses were higher when they saw a photo of their mother's face compared to a photo of an unfamiliar female face (Walton et al., 1992). When mothers were present but did not speak, 4-day-old newborns looked longer to their mother's face than to a stranger's face (Field et al., 1984). Similar results were found in 49 h olds, even when the individual smell of the mother was masked by a flavor (Bushnell et al., 1989). Pascalis et al. (1995) replicated those findings and, in addition, found that the preference for the mother's face disappeared when the outer facial features, such as the hair and chin contour, were covered by a scarf. Such a dominance of the outer facial features in recognizing mothers' faces was replicated in 19- to 25-day-old infants (Bartrip et al., 2001), while 35- to 40-day-old infants recognized their mothers' face when presented with inner features only.

One important requirement for recognizing the mother's face shortly after birth seems to be the simultaneous perception of the mother's voice and face. Sai (2005) reported that only newborns who experienced their mother's face and voice together recognized the mother's face 3–7 h after birth, while infants who saw their mother's face but did not hear her voice could not discriminate between their mother's face and an unfamiliar female face. These results suggest that experience with the mother's voice during pregnancy primes the infant's recognition of the mother's face and points to intermodal learning in very young infants.

What about the recognition of other faces? Early competency in face recognition has been observed in 4-day-old newborns. Infants were habituated to one face, and recognition was tested immediately after habituation and after a delay of 2 min by presenting the habituation face together with an unfamiliar face. At both testing times, the infants looked longer at the unfamiliar face, indicating recognition of the habituated face, immediately and after a 2-min delay (Pascalis and de Schonen, 1994). A more demanding challenge within face recognition is the ability to recognize faces in varied poses. To investigate this skill, 3 and 6 month olds were habituated to a single face in different poses that also varied in emotional expression. After 2 min and 24 h, the 6 month olds and the male 3 month olds recognized the habituation face despite the variations in poses and emotional expressions (Pascalis et al., 1998). Based on the results from behavioral studies and neurophysiological findings, Nelson (2003) concluded that face recognition is relatively robust at the age of 6 months. Despite the impressive face recognition abilities of infants, it is recognized that the face processing system undergoes development during the first decade of life (Schwarzer et al., 2003). Face recognition during the transition from infancy to childhood has been less investigated. The few existing studies show that when young children were tested with a small number of faces they show high recognition accuracy; e.g., 2 year olds made only few mistakes in recognizing a single face across variations in poses and emotional expressions (Brace et al., 2001). Similar findings were made in 3 year olds using two target faces (Freitag and Schwarzer, 2011).

Featural and Configural Processing

Whereas most investigators agree on the definition of featural processing of faces in terms of a concentration of a single facial feature, configural processing can be divided into three types (see Maurer et al., 2002): (1) sensitivity to first-order relations, i.e., identifying that a stimulus is a face because the features are

arranged with two eyes above a nose, which in turn is located above a mouth; (2) holistic processing, i.e., gluing together the features into a gestalt; and (3) sensitivity to second-order relations, i.e., perceiving specific distances among the features. In the following paragraphs, we describe the extent to which infants and young children show these three types of configural processing.

In principle, all studies demonstrating young infants' preferences for face-like stimuli indicate their sensitivity to first-order relational information in faces (see earlier text). For example, Simion et al. (1998a,b) reported that newborns could discriminate between schematic faces that consisted of small elements arranged in either a face-like or a non-face-like configuration and that they tended to prefer the face-like pattern. Thus, previous research indicates that sensitivity to first-order relations in faces exists from the beginning of life.

The extent to which infants process faces holistically as a gestalt was first studied by Cohen and Cashon (2001) and Cashon and Cohen (2004). Using a so-called switch design, the authors contrasted holistic processing with featural processing. First, they habituated the infants to two adult female faces. Then, the infants were tested with a familiar habituation face, a 'switch-face,' and a novel face. The switch-face was a composite of the two habituation faces, consisting of the internal features or a subset of internal features of one face and the external features of the other face. The faces in the habituation and test phases were presented either upright or inverted. To assess whether the infants used featural or holistic processing, it was crucial to determine whether they looked longer at the switch-face or the familiar habituation face. The authors reasoned that the infants would look longer at the switch-face only if they were processing more than the independent features and were integrating at least some of the internal and external features. However, if they were processing the facial sections independently, the infants would not respond to the switch-face. The results showed that holistic processing seemed to follow an N-shaped developmental pattern for upright faces and an inverted U-shaped pattern for inverted faces across an age range of 3–7 months. This means that the youngest age group, the 3 month olds, processed upright and inverted internal and external sections of faces independently of each other, i.e., by feature. Recently, however, Turati et al. (2010) investigated holistic processing of the top and bottom halves of faces in 3 month olds using a modified version of the composite face task. They showed that differentiation between the two top halves of faces was impaired when the halves were combined with new bottom halves in an aligned condition, compared to a condition in which the face halves were misaligned. Those results can be interpreted as an indication of holistic face processing of the top and bottom halves of faces. Thus, at 3 months of age, holistic processing of faces seems to be dependent on which facial sections (internal/external, top/bottom) are taken under consideration. In the study by Cashon and Cohen (2004), the 4 month olds processed both upright and inverted internal/external sections holistically, while the 6 month olds processed both upright and inverted external and internal sections independently of each other; i.e., featurally. Finally, the 7 month olds processed the upright internal and external facial sections holistically and the inverted sections featurally. Schwarzer et al. (2007) and Schwarzer and Zauner (2003) followed up the Cashon and Cohen study and investigated which parts of a face create a switch effect. They compared changes in the eyes or the mouth with changes in both the eyes and the mouth. The authors found that 8- and 10-month-old infants processed all of the changes in the face holistically, whereas 6 month olds processed eyes as features but integrated the mouth into the whole face. Four month olds processed both the eyes and the mouth as features. Thus, while it is assumed that 7- to 8-month-old infants process faces holistically, the results from younger infants are mixed. The majority of the results suggest that young infants tend to process faces by feature, rather than as a whole.

Holistic processing has also been demonstrated in older children (4 year olds) using a part-whole task (Pellicano and Rhodes, 2003). In this task, children learned to identify a set of faces and were then asked to identify single features separately and in the context of the whole face. They identified the features more easily and more correctly in the whole-face condition than in the separate condition, indicating holistic processing. De Heering et al. (2007) and Macchi Cassia et al. (2009) showed holistic processing in 3- and 4-year-old children using the composite task. Children more quickly and correctly recognized the top half of a face when presented with a misaligned bottom half, but were slower to recognize the top half of a face when the top half was aligned with the bottom half of a different face. However, when 2- to 5-year-old children were asked to categorize faces they did not categorize them holistically but, instead, categorized them by single features (Schwarzer, 2002). Thus, young children are sensitive to holistic changes in a face but are still unable to explicitly use holistic face information to categorize faces.

There are also studies demonstrating infants' sensitivity to second-order relations with the regard to perceiving specific distances among the features. Bhatt et al. (2005) habituated 5-month-old infants to a face in which the eyes were moved slightly up and the mouth was moved slightly down. After habituation, the infants looked longer at the unaltered face and failed to discriminate the faces when they were inverted. Similarly, Thompson et al. (2001) and Bertin and Bhatt (2004) provided evidence of infant sensitivity to second-order relations at 6 and 7 months of age. Leo and Simion (2009) showed that even newborns were sensitive to specific changes in a face. They demonstrated that newborns could discriminate upright Thatcher faces from non-Thatcher faces, although those faces differed only in their second-order configural information.

Pellicano et al. (2006) provided evidence of sensitivity in young children to the second-order relations of a face at approximately 4 years of age using the part-whole task. They found that children were better able to recognize facial features with the same configuration than corresponding facial features with new spacing, indicating sensitivity to changes in internal facial features. Macchi Cassia et al. (2011) revealed signs of sensitivity to second-order relations in 3-year-old children. They tested sensitivity to variations in the spacing of features in faces and non-face objects using

a two-alternative forced choice matching-to-sample task. Three year olds performed above chance on the face and non-face objects discrimination task but only when tested with larger spacing changes in a task that required no memory demands.

Taken together, previous studies on infant face processing suggest that young infants process all three types of configural information of faces. Sensitivity to first-order relations remains functional throughout development, whereas holistic processing and sensitivity to second-order relations only develops during the second half of the first year. The extent to which holistic processing and sensitivity to second-order relations are used in young childhood strongly depends on the demands of the tasks.

Role of Social Face Information in Face Processing

Faces comprise a variety of social information, including gender, age, emotional expression, and eye contact. Emotional facial expressions and gaze direction are highly relevant for nonverbal social communication in each age group and in infants in particular. Bowlby (1969), for example, reported that a smile on a caregiver's face induces the expression of joy in infants and, in turn, enhances the caring behavior of the adult. Particularly in situations that are unpredictable to infants, infants make use of their caregivers' emotional expressions to learn about a potential threat and to regulate their behavior in relation to the caregivers' emotional facial expression (e.g., Sorce et al., 1985).

The processing of emotional expression does not only impact infants' social communication, but also seems to influence infant processing of facial identity. For infants and young children, results indicate that emotional facial expressions can enhance face recognition (Pascalis et al., 1998; Turati et al., 2004). Seven-month-old infants who were habituated to a frontal view of a face recognized the habituation face in a 3/4-pose only when it was presented with a smile or anger expression but not when it was presented with a neutral expression (Gross and Schwarzer, 2010). The influence of emotional expression on face recognition was also shown in 3 year olds who were more proficient at recognizing faces in varied emotional expressions when the faces were encoded with smile or anger expressions compared to neutral expressions (Freitag and Schwarzer, 2011). These results suggest that emotional facial expressions enrich a face, facilitating the processing of face identity and making face recognition more robust against variations in poses or emotions. This interpretation is supported by neurophysiological data indicating that faces expressing emotions activate more complex and interactive brain areas compared to faces with neutral expressions (Vuilleumier and Pourtois, 2007).

Gaze direction and eye contact are also crucial for social communication (see Frischen et al., 2007). For infants, it is an important developmental goal to attend to the gaze of their interaction partners and to learn to coordinate their own visual attention with that of others. The ability to focus with an interaction partner on the same object at the same time enables shared attention (Tomasello, 1999), which can be seen as a general principle for social learning. It was reported that newborns tested 37 h after birth prefer to look at faces with eyes open compared to eyes closed (Batki et al., 2000). Newborns are also sensitive to the gaze direction of other people and prefer to look at faces with direct gaze (Farroni et al., 2006) compared to averted gaze. The finding that infants discriminate gaze direction in others is supported by the result that the brain activity of 4 month olds was substantially different for faces with eye contact compared to faces with averted gaze (Johnson and Farroni, 2003). At 3 months of age, infants begin to follow the eye movements of a social agent with their own eyes. While young infants gaze following is limited to situations in which the social agent's gaze is directed to objects very close to the infant, gaze following occurs with more distant objects at approximately 6 months of age (Butterworth and Itakura, 2000). The ability to coordinate gaze with that of others becomes robust at the end of the first year (Farroni et al., 2002).

The extent to which infants and toddlers follow the eye movements of others is also influenced by situational aspects. For example, it was shown that infants respond more often to the eye movements of others when they had previously been interacting directly (Collicott et al., 2008; Johnson et al., 1998). Another example showed that young children focused on the eye movements of others when they had to find an object that was hidden from their own perspective (Moll and Tomasello, 2004).

Role of Experience in Face Processing

Previous research has demonstrated that experience with faces plays a crucial role in young children's processing of faces. In the following, we elucidate how early visual experience shapes the functionality of the face processing system and how the specific faces to which infants are exposed refine the recognition of faces.

Studies with patients deprived of early visual experience by bilateral cataracts showed that visual experience during the first weeks and months of life is critical for the normal development of some, but not all, aspects of face processing (see Mondloch et al., 2010, for an overview). For example, infants treated for congenital cataracts after 6 weeks of age showed a pattern of face preferences on the day that they could first see similar to that of newborns. This result indicates that the postnatal sensitivity to first-order relations (see earlier text) is driven by visual input but does not require early visual input (Mondloch et al., unpublished data, cited by Mondloch et al., 2009). However, such an early visual deprivation was also associated with permanent deficits in the later development of face processing, such as in the holistic processing of faces (Le Grand et al., 2004) and in the processing of second-order relations in faces. For example, adult patients deprived of early visual experience had difficulty distinguishing faces that differed only in the spacing of the features (Le Grand et al., 2001) and in the recognition of faces from a novel point of view (Geldart et al., 2002). In contrast, later development of the processing of facial features was not impaired. They were able to distinguish faces that differed only in the shape of

individual features or in the contour of the external face (Le Grand et al., 2001).

The role of experience in the development of face processing is also evident when exploring how experience with individual faces or certain face categories affects the recognition of faces in children with normal early visual experience (see Pascalis et al., 2011, for an overview). Most of the studies have focused on the role of the infants' specific experience with faces on the recognition of faces belonging to their own or another species or race. With regard to species, Pascalis et al. (2002) demonstrated that 6 month olds could recognize different human and monkey faces, whereas memory for individual monkey faces disappeared at 9 months of age. However, this loss was attenuated when infants were trained to recognize monkey faces (Pascalis et al., 2005). Scott and Monesson (2009) showed that not only experience with monkey faces but also the development of exemplar-based individual memory could prevent such a loss. They trained 6–9 month olds in three different conditions. One group was trained at the individual level (each monkey face was individually labeled), a second group was trained at the categorical level (each monkey face was labeled 'monkey'), and a third group was shown monkey faces without labels. Only the infants trained at the individual level maintained the ability to discriminate among the monkey faces at 9 months of age. Infants who were otherwise trained lost the ability.

With regard to race, similar results on the effects of experience have been revealed. Whereas 3-month-old Caucasians discriminated between faces from four ethnic groups (African, Middle Eastern, Chinese, and Caucasian), 6-month-old Caucasians discriminated only between Chinese and Caucasian faces and 9-month-old Caucasians did so only within Caucasian faces (Kelly et al., 2007). Kelly et al. (2009) found a similar developmental course for 3-, 6-, and 9-month-old Chinese infants when presented with Chinese, Caucasian, and African faces. Recently, infants' specific experiences with other races have been shown to reverse this other-race effect. Heron-Delaney et al. (2011) demonstrated that exposing Caucasian infants to Chinese faces through perceptual training with picture books for 1 h between 6 and 9 months of age enabled the Caucasian infants to maintain the ability to discriminate Chinese faces at 9 months of age. A recent study by Spangler et al. (2012) produced similar results. Here, the other-race effect of Caucasian infants at 3, 6, and 9 months of age was investigated longitudinally using Caucasian and African faces. The authors found a similar ability to differentiate African faces at all ages, even at 9 months of age, whereas another sample of 9-month-old Caucasians were not able to differentiate African faces. The results were interpreted to mean that repeated exposure to African faces in the longitudinal sample at 3 and 6 months seemed to provide sufficient experience with African faces to prevent the onset of the other-race effect at 9 months of age.

Thus, it can be concluded that, according to Nelson's (2001) concept of perceptual narrowing, training or experience with faces of other races or other species slows or modifies the fine-tuning toward faces of one's own race or species. Such fine-tuning, occurring with increasing experience, can be related to the face model of Valentine (1991). He proposed that faces are encoded and represented in a multidimensional cognitive map, a perceptual face space. In this space, individual faces are coded relative to the average of previously encountered faces. The distance among faces represents their perceived similarity. Typical faces are represented close to each other, while distinctive faces are more spread out in the face space. Pascalis et al. (2011) assumed that face spaces are tuned toward faces present in the environment and are less effective at processing faces from different ethnic groups or different species. The authors suppose, according to Furl et al. (2002), that frequent exposure to a certain face category, such as a certain race or species, could cause a warp in the face space that enhances the differences in faces within a familiar and often experienced face category, leading to an advantage in differentiating such faces. At the same time, this space limits the quality of the face representations for other-race or other-species faces, leading to low differentiation between them.

Whereas a huge amount of research has focused on the role of experience in infant face processing, far less data are available for the following years of childhood. One of the few studies, for example, Sangrigoli and de Schonen (2004), demonstrated the other-race effect in 3 year olds. However, this study also showed that the effect was highly fragile at that age. When faces were presented for 1000 ms, the other-race effect appeared, but when the presentation time was reduced to 500 ms the effect disappeared. This might be because developing face processing abilities are highly intertwined with concurrently developing general cognitive abilities at that age. This can complicate the assessment of face processing abilities and can produce inconsistent results. Future research needs to examine the role of experience in face processing while considering the general cognitive abilities of children.

Face Recognition Models: Computational Approaches

Zhen Lei and Stan Z Li, Chinese Academy of Sciences, Beijing, China

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Face recognition by machine is a technique that automatically recognizes human beings from images. It is a cross topic involving techniques from pattern recognition, computer vision, image processing, and so on. This article presents an introduction to face recognition from a computational model view. The concept of face recognition is briefly introduced. This is followed by a description of four main computational modules in the process, namely face detection, face normalization, face feature extraction, and feature matching. Finally, existing challenges and future research directions in real world face recognition are discussed.

Face Recognition

Face recognition is a task that humans perform routinely and effortlessly in our daily lives. Face recognition by machine is a computational technique that automatically recognizes human beings from images. Aimed at different applications, face recognition can be roughly categorized into face identification and face verification. Face identification is to find the identity from a set of registered candidates whose stored face images are the most similar to the input face image. Face verification is used to examine whether two face images come from the same person or not. In real world applications, there are also cases that involve simultaneous face identification and verification. For example, in a video-based watch list surveillance system, the captured face image is both identified (to whom it belongs) and checked to see if it is on the watch list.

In the past several decades, face recognition has attracted much attention and has been developed rapidly. The face recognition test report in Phillips et al. (2010) showed that the state-of-the-art face recognition algorithms have boosted face recognition performance by 10–100 times better than the best performances in years 1997 and 2002. This is solid proof that face recognition techniques have made great progress. The report also indicated that face recognition with still frontal face images captured in a controlled environment has achieved excellent performance, while its performance in uncontrolled conditions is still far from satisfactory. Phillips et al. (2010) also found that some of the algorithms can already outperform human participants in recognizing faces, which is a very promising achievement for the face recognition research field.

Generally speaking, current mainstream face recognition methods consist of the following four modules (see Figure 1): face detection, face normalization, face feature extraction, and feature matching. Given an image, the face is first detected and segmented; operations of alignment and preprocessing are then applied to normalize the face image; salient face features that are useful and robust for face recognition are then extracted from the normalized face; finally, the extracted features are compared with the templates stored in face database to compute the similarity between different faces.

Face Detection and Landmark Localization

Face detection is the first step for whole face biometrics, and its accuracy greatly affects the performance of sequential operations. Regarding this issue, the algorithm proposed by Viola and Jones (2004) is probably the most successful and pioneering contribution. In their method, a cascade of Adaboost classifier with Haar-like feature is designed for face detection. The Haar-like feature can be fast computed by integral image technique. The Adaboost learning is able to select most effective features from a large feature pool to form a strong classifier. With the cascade structure (Figure 2), most nonface samples are rapidly rejected at the former stages, so that face detection process is greatly accelerated. Nowadays, not only the frontal face detection but also many more multiview (or multipose) face detection algorithms have been developed using a similar framework.

The methodology of face detection can also be applied to landmark (e.g., eyes, nose tip, and mouth) localization, which

Figure 1 Face recognition flowchart.

Figure 2 Cascade structure of face detection. The nonface samples are rapidly rejected by the former classifiers.

can then be utilized to face geometrical normalization. Active Shape Model (ASM) and Active Appearance Model (AAM) (Cootes et al., 1995) are also popular approaches to locating facial landmarks. In ASM, facial landmarks are first detected by searching local regions, and then these landmarks are jointly optimized by global shape constraints. In AAM, not only the shape constraint but also the texture constraint are utilized to improve the accuracy of localization.

Face Normalization

Face normalization includes face geometric and photometric normalization. The geometric normalization transforms the face image into a predefined size so the pose and scale variations can be reduced. The photometric normalization process extracts the intrinsic face information so the external illumination variation is removed. Some prevailing processing methods include histogram equalization, self-quotient image, Retinex, logarithmic total variation, and so on. Many of these methods focus on extracting the face reflectance component, which is considered as the intrinsic factor and is invariant to illumination variation.

Feature Extraction

After the preprocessing steps such as face detection and face normalization, we move to the next module to extract discriminant features for face recognition. In real application, the face images are easily affected by expression, lighting, aging, and so forth. Therefore, how to extract features that are robust to these variations is a critical issue for face recognition.

Up to now, many face representation approaches have been introduced, which can be roughly categorized as subspace-based holistic features and local appearance features (Li and Jain, 2011). Holistic methods model the face image from a global view and extract the features based on the whole image. In contrast, local descriptors capture the local structures of the face image, respectively, and then these features are combined to represent the whole face.

Face images reside in a subspace of the input image space. For example, a 60×60 grey image with 3600 pixels can express a large number of pattern classes, such as trees, cars, and faces. However, among this huge number ($256^{3600} > 10^{8100}$) of possible configurations, only a tiny fraction corresponds to faces. Therefore, there is high redundancy in the pixel-based image representation; it could be greatly reduced when only the face patterns are considered. Subspace learning is a tool that finds the embedded subspace of a specific object (e.g., face) from the original image space.

Typical subspace learning methods include Principal Component Analysis (PCA) (Turk and Pentland, 1991) and Linear Discriminate Analysis (LDA) (Belhumeur et al., 1997). PCA provides an optimal linear transformation from the original image space to an orthogonal eigenspace with reduced dimensionality in sense of the least mean square reconstruction error. PCA was first applied in face recognition in the 1990s and greatly promoted face recognition development at the time. PCA successfully extracts the most distinct variations of different faces and reduces the noise components of face images so the face recognition performance is significantly improved. Given a data set $X = [X_1, X_2, \ldots, X_N]$, where N is the number of samples, PCA aims to learn projections (PCs) W that maximizes the total covariant matrix $S_t = \sum_{i=1}^{N}(X_i - m)(X_i - m)^T$, where m is the mean vector over the sample set. The PCs can be derived by solving the eigenvalue problem $S_t W = \lambda W$ with its leading eigenvalues.

Although PCA is optimal for modeling the face distribution, it may not be the best for classification because it fails to utilize any class label information. On the contrary, LDA is proposed to find a subspace that gathers the samples from the same person and meanwhile enlarges the margin among different persons. In particular, it seeks a linear transformation that maximizes the ratio of between class variance to within class variance. The between-class scatter matrix S_b and the within-class scatter matrix S_w are defined as follows,

$$\begin{aligned} S_b &= \sum_{i=1}^{c} N_i (U_i - U)(U_i - U)^T \\ S_w &= \sum_{i=1}^{c} \sum_{X_k \in C_i} (X_k - U_i)(X_k - U_i)^T \end{aligned} \quad [1]$$

where U_i is the data mean of the ith class; U is the data mean over the total data set. N_i is the number of samples in ith class. By solving the generalized eigenvalue problem $S_b W = \lambda S_w W$, the solution of LDA can be obtained with its leading eigenvalues. In practice, because of the limited sample size and high dimension data, the within class scatter S_w is usually singular. One possible way is first to reduce the dimension with PCA and then apply LDA to find the discriminant subspace for classification.

Local appearance features, as opposed to holistic features like PCA and LDA, provide another alternative to face representation. They are extracted from the local regions of face images, respectively, and hence are usually more robust to local changes (e.g., expression and lighting variations) than holistic features. Among all possibilities, Gabor and local binary patterns (LBPs) are two representative features. Daugman (1985) first proposed a 2D Gabor filter and successfully applied it to accurate iris recognition. The profiles of Gabor filters mimic the human visual perception system, thus Gabor is expected to be effective to represent face images in

Figure 3 Face image (a) and its Gabor magnitude response image (b).

a biological manner. Moreover, Gabor wavelets have also proved to be optimal for measuring local spatial frequencies mathematically. By applying a bank of various Gabor filters at different scales and orientations, it is capable of capturing local structures corresponding to specific spatial frequency (scale), spatial locality, and selective orientation. Many well-known face recognition methods like Elastic Bunch Graph Matching (Wiskott et al., 1997) and Gabor Fisher Classifier (Liu and Wechsler, 2002) adopt the Gabor feature as face representation, validating the effectiveness of Gabor representation. Particularly, Gabor magnitude response is more popular in face recognition since it is more stable to local image variations. Figure 3 shows the magnitude images filtered by a bank of Gabor filters.

LBP (Ahonen et al., 2006) is another simple, yet effective face representation method. It models the pixel relationship in the neighborhood. Figure 4 illustrates the process of basic LBP operator. For each image pixel, the neighboring pixels are compared with the central one, and the difference is thresholded and concatenated into a binary string. This string can be converted into a decimal value, which is named an LBP label. For the sake of accuracy and generality, usually the distribution of LBP labels within certain regions is calculated to produce a local histogram, and all local histograms are concatenated to form the global representation. Due to its binary operator, LBP is invariant to monotone transformation of images and is robust to illumination changes to some extent. Nowadays, many LBP variations like Multi-Block LBP (Liao et al., 2007) and Gabor volume-based LBP (Lei et al., 2011) have been proposed to further improve the discriminative power of LBP descriptor.

The holistic and local features can also be used together to boost the face recognition performance. After extracting local features, holistic-based methods like LDA are applied on these extracted local features to find a discriminant subspace to classify faces. This is one of the state-of-the-art algorithms for face recognition.

Figure 4 Local binary pattern (LBP) extraction.

Recently, Kumar et al. (2011) have proposed attribute and simile representations for face recognition. The attribute means the describable aspects of visual appearance (like gender, race, and age) and uses binary classifiers to recognize them. For simile, the test image (regions of the image) is compared to the images (regions) in a reference set, and the similarity between them is used as the face representation. The attribute and simile are finally combined to form a compact face description. This representation is shown to be effective and robust to real word face recognition.

Feature Matching

In the feature matching phase, efficient classifiers should be designed to measure the similarities of different samples and judge whether two images come from the same person or not. In many face recognition applications, the number of identities (classes) is changeable, so many traditional classification methods in pattern recognition cannot be directly applied to face recognition. The most popular and flexible classification method is the nearest neighboring classifier, which computes the similarity (or distance) of sample pairs using a specific metric. Classification result is made by finding the class label with the smallest distance. By transforming face recognition to a two-class classification problem, other popular classification algorithms can also be applied to face recognition. For example, Moghaddam et al. (2000) propose the concepts of intra- and interface samples space. This converts the multiclass face recognition problem to a two-class one by classifying whether two images come from the same person or not. In this way, some efficient classifiers like Adaboost and support vector machine (SVM) can be used to distinguish this sample pairs.

Recently, sparse representation-based classifier (SRC) (Wright et al., 2009) has been introduced in face recognition. It treats face recognition as the problem of searching the sparse combination of templates in a database to represent the input image (Figure 5). SRC assumes that images in the database, which share the same identity with the input image, would make more contributions to the representation. Because of the sparse characteristic, the SRC is robust to facial appearance variations, especially when the face is occluded. To guarantee a high accuracy, SRC requires the gallery set to contain as many diverse face images (including different illuminations, expressions, occlusions, etc.) as possible. Yet in real world applications, it is very difficult to collect many face images, which limits the application of the SRC method.

Challenges in Face Recognition

Variations such as lighting, pose, and occlusion are still main issues that affect the face recognition performance. For cooperative scenarios, frontal face detection and recognition in normal lighting environment is a reasonably well-solved problem. For noncooperative scenarios, the non-frontal face detection has been well solved, but the unconstrained face recognition is still an open problem. The face images in these scenarios (Figure 6) always suffer from one or several factors like lighting, pose, occlusion, low resolution, blur, and so forth, which lead face recognition to be a challenging task.

Face recognition across aging is another unsolved problem. Current face recognition performs well when the age range is within 5 years. However, the performance decreases dramatically when the range exceeds 10 years. Aging is challenging because it is a combination of intrinsic facial variation and external factors including expression, pose, and lighting variations. Addressing the aging problem means it must address all other variants as well. One possible way is to use a 3D face model to simulate the face appearance changing across aging and synthesize the virtual face images with similar age for face recognition. Another approach is to match the two age-

Figure 5 Process of sparse representation classifier. The test image is represented as a sparse linear combination of training images. The responses of the images that are of the same identity with the test image usually have stronger responses than others.

Figure 6 Face images captured from a face video surveillance system. There are variations on lighting, pose, occlusion, blurring, and so forth.

separated images directly. Both age-invariant feature extraction and effective classifier learning are open problems.

Abstract

Face recognition can be defined as the ability to identify an individual from gazing only at their face, or an image of their face. This ability remains largely unaffected even with extreme changes in lighting level, viewing angle, and distance as experienced in daily life. In cases of brain injury, individuals may develop an inability to recognize previously familiar faces – a condition known as prosopagnosia. The observation that prosopagnosic individuals never recover this function argues for the existence of a specialized brain circuitry that deals with this important stimulus category. Physiological studies in primates originally identified cells responsive specifically to faces, prompting the search for similar tissue in humans. Noninvasive brain blood flow and neurophysiological studies indicate that this is also the case in humans. These data also suggest that the ability to recognize a face proceeds independently and in parallel with the ability to read facial expressions and gestures, and that these functions are handled by a so-called 'extended face network' in the brain. There is debate as whether 'face-specific' brain regions respond specifically to faces, or whether they merely reflect the activity of neurons trained to individuate exemplars from object categories with highly similar member items. It is important to note that this ability develops in early life in a maturing brain.

Behavioral Studies, Early Theoretical Models, and Investigations in Brain-Injured Individuals

Groucho Marx once said, "I never forget a face, but in your case I'll make an exception." This statement is remarkable in that we cannot actively choose not to recognize or remember a face. This process proceeds to completion without a conscious effort on our part, and the complexity of this operation only becomes apparent when it breaks down, e.g., when a face appears familiar, but cannot be associated with a name or context of the original interaction. What is truly remarkable is that people can still recognize individuals who have not been seen for long periods of time and who have also changed their appearance as a function of aging.

After birth, probably one of the first few objects seen most often is a face. Infants actually pay more attention to faces than other stimulus categories (Morton and Johnson, 1991). Being able to recognize the face of a caregiver is important – the infant is totally dependent on them for nourishment and shelter. Facial recognition in children as young as 4 years of age has been postulated to be qualitatively similar to that of adults (McKone et al., 2009), however, different brain responses to various face-processing tasks show differential changes from childhood to adolescence, as indicated by their impaired recognition performance when the faces are presented upside down (Taylor et al., 2004). The inability of adults to successfully recognize inverted faces (Yin, 1969) had been demonstrated previously as a hallmark of specialized processing of the upright face. While it has always been thought that face-processing skills in adults are stable across the lifespan, recent evidence suggests that face naming skills peak during the early twenties, whereas the ability to learn and recognize faces without having to name them peaks in the early thirties of age (Germine et al., 2011).

Studies in adults suggest that successful face recognition proceeds in a series of stages, based on behavioral studies of normal individuals and those with brain injury. This well-known and now classic model of familiar face recognition was first proposed by Bruce and Young in the year 1986. Face perception, or detection, i.e., the ability to see a presented object as a face, and not a chair, formed the first stage of this process, the so-called structural encoding stage. The face and its features are processed holistically, with the output of the structural encoder feeding the so-called face recognition units (FRUs). At this stage, the familiarity judgment is made. Next, FRU output activates so-called person identity nodes (PINs), allowing the information previously stored about that individual (e.g., gender, age, profession, relationship to observer, usual interaction context – i.e., work or home, specific details of pleasant or unpleasant previous contact, etc.) to be accessed. Finally, the output from the PINs activates the name representation for that individual. This multipart familiar facial recognition model has in the past explained many errors in facial recognition seen in everyday life (e.g., the face is familiar, but the person's name cannot be accessed), and in cases of brain injury. A second pathway in Bruce and Young's model dealt with the processing of facial expressions, however, at the time of exposition, this was not a well-developed part of this model.

Prosopagnosia is the inability to recognize previously familiar faces, and can occur following a stroke or as a result of a brain tumor. The individual can no longer recognize even the faces of their spouse or children. Prosopagnosia can co-occur with other visual deficits, such as a loss of color vision (achromatopsia) and an inability to recognize everyday objects (object agnosia) (Meadows, 1974). These visual deficits can co-occur in brain injury, as brain regions selectively processing these stimulus attributes are located near one another. Apperceptive prosopagnosia is so named because the source of face recognition difficulty occurs largely to disruptions in basic visual perception. This form of prosopagnosia can co-occur with object agnosia, and patients often describe a degraded, fragmented visual scene. Alternatively, basic visual perception may be fairly intact, and a face is seen as a 'face,' but the individual's name or their personal details cannot be accessed, i.e., associative prosopagnosia. The ability

to recognize facial expressions is dissociable from facial recognition (Humphreys et al., 1993), and this dissociation was originally proposed in early models of face processing (Bruce and Young, 1986).

Individuals with prosopagnosia do not appear to recover the ability to recognize faces once the critical areas of the brain have been damaged. Face recognition may be 'hardwired' in the brain even in the absence of postnatal experience with faces, as illustrated by the intriguing case of prosopagnosia in a 16-year-old boy who sustained his brain injury at one day of age (Farah et al., 2000). Even more intriguing are the documented cases of 'developmental prosopagnosia,' where in the presence of apparently normal brain structure individuals are born with the inability to recognize faces, an ability that also appears not to develop in life (Le Grand et al., 2006). The different forms of prosopagnosia have stimulated researchers to hunt for specialized brain circuitry that processes faces. Additionally, recordings from single cells in visually sensitive regions of monkey brains show specific responses to faces, and not other object classes (for a review, see Desimone, 1991; Milders and Perrett, 1993). Given that humans and monkeys are both social animals, and that faces are an important stimulus in this context, it was thought likely that the human brain possesses brain cells with similar response properties.

Neuroimaging and Neurophysiological Studies and a Brain Network for Face Processing

In the latter part of the twentieth century many human physiological studies were dedicated to investigating the neural mechanisms underlying facial perception (see review by Haxby et al., 2000). This was prompted, in part, by the development of neuroimaging techniques such as positron emission tomography (PET) and, more recently, functional magnetic resonance imaging. Both methods effectively measure focal changes in brain blood flow during perception and cognition. One of the first investigations of face perception and recognition was performed by Justine Sergent working at the Montreal Neurological Institute in 1992 (Sergent et al., 1992). Sergent and her colleagues performed a PET study examining differences in cerebral blood flow when healthy adults viewed pictures of faces and discriminated between various facial attributes. For example, subjects made gender judgments (deciding whether a face was male or female), remembering if a particular face had been shown to the subject previously, and so on. The blood-flow patterns in these conditions were contrasted to conditions where subjects viewed visual material such as gratings (grids of black and white lines). These studies identified regions of the occipital and temporal lobe on the underside of the brain as being selectively active when subjects viewed and discriminated between faces. Since then many investigators have followed suit and studied other aspects of facial processing (reviewed by Haxby et al., 2000), and the studies show concordance with this initial pioneering investigation. Taken together the literature to date suggests that the brain possesses parallel pathways that deal with facial identity and facial gesture, respectively (Allison et al., 2000), and that there is a distributed network of brain structures that work together to handle these different functions (Haxby et al., 2000), as depicted in **Figure 1**. While 'face-selective' regions in both hemispheres possess the capability to process faces, it is the right hemisphere that appears to be more important for this process. In prosopagnosia, for example, if the lesion occurs on one side of the brain it is usually on the right side (De Renzi et al., 1994).

Figure 1 The distributed brain network for processing faces as proposed by Haxby, J.V., Hoffman, E.A., Gobbini, M.I., 2000. The distributed human neural system for face perception. Trends in Cognitive Sciences 4 (6), 223–233 from an extensive review of the literature. The distributed brain network consists of two major parts. A core system performs visual analysis of faces and consists of the inferior occipital gyri (IOG), the lateral fusiform gyrus (lat FG) and the superior temporal sulcus (STS). The IOG encodes basic facial features, the lat FG is thought to deal with invariant aspects of faces, which aid in the gleaning of unique identity. The STS deals with the perception of dynamic aspects of faces such as eye gaze and facial expression changes, as well a lip movement. An extended system derives input from the core system and performs further face processing and interacts with other brain systems. The extended system includes the anterior temporal lobe (ant Temp), which takes input from the fusiform gyrus so that personal identity, name and biographical information can be linked to the seen face. Other parts of the extended system include the intraparietal sulcus (IPS) (thought to deal with the aspects of direction attention in one's space), the auditory cortex (AC) (assisting in speech perception), and the limbic system and the insula (dealing with emotional aspects of the face and affective context).

Our understanding of what is active in the human brain when a face is being evaluated clearly has evolved as a result of the now substantial neuroimaging and neuropsychological lesion literature on face processing. For example, the extended face-processing network (**Figure 1**) now includes explicit brain structures that are linked to particular face recognition processes. Additionally, the alternate pathway for processing facial expression has now been more completely specified, relative to the original model proposed by Bruce and Young in 1986.

Blood flow and neuropsychological lesions studies clearly show which brain regions are active, however these methods cannot characterize these changes well over the course of time. Recordings of electrical or magnetic activity of the brain electroencephalography or magnetoencephalography have resolution to thousandths of a second (millisecond) and can

therefore chart the dynamics of face perception processes accurately. A brain response to seeing a face occurs at around 1/5th of a second, which has been named as N170 (Bentin et al., 1996). The robustness of the N170/N200 under a large number of perceptual manipulations and the seemingly automatic way in which the response is generated suggests that this may be a neural correlate of the structural encoder of Bruce and Young's (1986) original model, and is a vital first part in the visual analysis of the face in Haxby et al.'s model (2000). The N170 data are consistent with behavioral studies of face perception, where healthy subjects can readily detect faces relative to other object categories, despite stimulus degradation, fragmentation, rotation, inversion, manipulations of light and shade, and so on (Bentin et al., 1996). A similar neural response can also be recorded directly from the surface of the fusiform gyrus in human brain in epilepsy surgery patients (so called N200), and like its scalp counterpart occurs irrespective of whether the observer attempts to recognize the face or not, and is largely independent on lighting conditions, size, orientation of the face, gender, or familiarity of the face (Puce et al., 1999). Brain activity that follows the N170/N200 is more likely to be attributable to higher order processes such as recalling the face or characterizing it according to some category (Puce et al., 1999).

Despite our excellent abilities to recognize faces under varied environment, in the laboratory setting facial recognition abilities can be challenged and be shown to be impaired under different extreme condition. Individuating one person's face from another requires that the features that are unique to that particular (familiar) individual are extracted and matched to a preexisting 'template.' Manipulations that impair our ability to extract subtle spatial differences will affect successful facial recognition. For example, Groucho Marx had a very idiosyncratic and easily recognizable face (see **Figure 2**). Yet, when he is upside down he is more difficult to recognize (compare **Figure 2(a)** with **Figure 2(b)**). Similarly, a negative image may make a previously familiar face unrecognizable (**Figure 2(c)**). Similarly, manipulations of spatial frequency content or amount of detail of the face can also impair facial recognition (**Figure 2(d) and 2(e)**). Under extreme conditions such as these we are forced to rely on idiosyncratic, incidental details that might accompany the face, such as the cigar and moustache so that we have learned to associate with Groucho Marx's face. Experimental manipulations such as these also help to emphasize how expert we are with identifying faces in the natural setting – the process is effortless and automatic.

On a daily basis, in natural conditions, our expert ability to discriminate between individual faces is based on detecting changes in subtle spatial configurations in a homogeneous object category, unlike any other object category dealt with on a daily basis. Our specialized facial recognition skills are so honed that behavioral studies have repeatedly demonstrated an own-race advantage for facial recognition across different ethnic groups, i.e., Caucasian, Asian (Brigham, 1986). These data suggest that there really might be a basis for the often-heard comment from travelers that the faces of people of other races look alike. Different ethnic groups have idiosyncrasies in their facial features that an individual member of that particular group learns to differentiate. The expertise that develops with the individual's own ethnic group may hence not necessarily be generalizable to another ethnic group. It has been said that the same type of bias might apply to viewing individuals in one's own age range also.

Does 'Face-Specific' Cortex Participate Only in Face Processing?

Are faces a special stimulus category? There is no doubt that we are experts with faces. However, there is debate about the nature of this expertise, and there are currently many unanswered questions regarding these issues. For example, do 'face-specific' regions of the brain deal only with faces, or are they also active in individuals who are experts with other object categories? i.e., are these neurons functioning specifically for detecting and recognizing faces, or are they a more general expert 'individuator' of categories of objects with highly similar member items (Gauthier and Logothetis, 2000)? Is the expertise with faces, and associated brain circuitry, that develops with the developing brain throughout childhood, different to expertise acquired with other stimulus categories in adult life?

How can these various interrelated processes be disentangled, given that we cannot test people who do not have a lifetime's exposure to faces? There are a number of approaches that are currently being undertaken in order to try and unravel these issues. First, some insight may come from studying patients with developmental prosopagnosia (Le Grand et al., 2006). This is an extremely rare disorder, where

Figure 2 The many faces of Groucho Marx. (a) The unaltered face; (b) an inverted orientation; (c) inverted gray-scale palette; (d) removal of the high-spatial frequency content of the image; and (e) removal of the low-spatial frequency content.

the individual has never developed the ability to recognize faces. Physiological and behavioral studies of face and object recognition in these individuals relative to both healthy and brain-injured subjects may shed some light on these questions. Second, face perception and recognition studies using cutting-edge neuroimaging techniques may be helpful. Direct recordings of electrical activity from the brain indicate that face-sensitive regions exist in a patchy mosaic with regions responsive to objects, and to words, for example. The relatively coarse spatial resolution in most neuroimaging studies to date could produce blood-flow measures containing contributions from different kinds of category-specific regions, making it difficult to evaluate exactly how these brain regions deal with facial information. Studies of facial recognition performed with (high field strength) functional MRI combined with recordings of the electrical activity of the brain in the same subject may finally shed some light on why it is impossible to forget a face, despite our best attempts to do so. Finally, many investigators are turning to the developing brain for answers to these questions. There are many knowledge gaps related to how the young human brain develops and hones its facial recognition skills from infancy to adolescence.

Abstract

In this contribution, we present theories discussing the origin and function of facial emotion expressions, research regarding their neural architecture, evidence for individual differences, and applied measurement methodologies. We then describe a series of assumptions regarding the factorial structure of facial emotion expression ability, showing that all of these postulations still need comprehensive empirical research in order to better understand individual differences in facial expressivity. Finally, we discuss the nomological net surrounding the production of facial emotion expressions including the relation of this ability with related skills, such as the ability to perceive emotion cues from faces.

For over a century scholarly literature has recognized that facial expressions play a key role in humans' communication of affect. Since Darwin's classic book, *The Expression of Emotions in Man and Animals*, the scientific reflection on spontaneous and voluntary facial activity has inspired a series of currently unresolved debates over the origin and function of facial emotion expressions in humans. Many researchers (e.g., Barrett, 2011) have strongly questioned that the *prototypic* emotional expressions – *fear*, *sadness*, *disgust*, *anger*, *happiness*, and *surprise* – are biologically hardwired, have well-defined functions for human survival, and thus exist in everyday life. Instead researchers have asked whether they "have created a science of emotional symbols by routinely using *prototypical expressions* in experiments" (p. 402, italics added).

In this article, we review debated theoretical positions over the origin of facial expressions and emphasize that a contemporary view on the nature of facial emotion displays should also recognize that to a strong degree facial expressions are voluntarily used to shape social interactions and that facial displays are socially learned: "Emotional expressions might be learned and, like other symbol-based communication that is socially learned, this would be evolutionary significant, immediately functional in individual instances, and adaptive for a species" (Barrett, 2011: p. 406). Because expressions are assumed to be, to a strong degree, defined by culture and interpersonal interactions, a contemporary view on emotion expressions recognizes within-emotion variability across persons, situations, and cultures as well as between-emotion similarities in facial displays. Such variations were also recognized by Darwin (1872/1965) and there is a growing account for such variability in the recent scientific literature (see, e.g., Barrett, 2009; Reisenzein et al., 2013).

In addition to theoretical considerations regarding the origin, nature, function, and neural bases of facial emotion expressions, we will stress the role of facial displays in everyday communication and define the voluntary production of facial expressions as a basic socioemotional competence that can and should be measured as a prominent individual differences construct. We will review the literature on the nomological net of facial expressivity and indicate that a multivariate and psychometric approach is needed to assess emotion communication ability via faces and its correlates in a conclusive way.

Theories on Facial Expressions of Emotion

Particularly Allport (1924), Tomkins (1962), Ekman (1972), and Izard (1971) theorized that facial emotion expressions are shaped throughout humans' evolutionary history and play a functional role in humans' adaptation to the physical and social environment. This functionalist interpretation of facial expressions has been widely accepted in later research and proponents have emphasized the need for studying spontaneous expressions. From the theoretical point of view that emotions are discrete, research suggests that prototypical emotion-specific response configurations will occur in the face as a consequence of the emotional experiences of that organism (e.g., Ekman, 1992a). In parallel, sociobiologically oriented theories emerged, suggesting facial expressions are purely social signals used for strategic or deceptive purposes (Dawkins and Krebs, 1978). These theories accentuated the important role of emotion displays in social communication. However, the cultural stereotype of affect displays, but also recent evidence based upon a comparison of sensory acquisition during fear versus disgust expressions (Susskind et al., 2008), to some extent support the functional utility of facial emotion expressions.

Hence, contemporary theorists argue that expressive signals can only be successfully used for strategic communicative purposes in a perspicuous manner because they are also often states of the organism. Scherer (2009a) defined *pull factors* of expression as voluntarily produced signals that are culturally coined and have specific structures that can be well understood by others. Furthermore, it is assumed that *pull factors* produce highly similar outputs like *push factors*, which are factors determined by the internal state of the organism. Thus, Scherer (2009b; also Scherer et al., 2013) emphasized that emotion expression is multifunctional; this is in line with Bühler's postulation regarding the trifold facets of signals: signals that operate like a *symptom* can be understood as a *symbol* and are often used as an *appeal* (Bühler and Goodwin, 1990). Scherer (2007) further suggested that emotion expressions have a strong strategic aspect which is more or less pronounced depending on the situation and that the *voluntary* and *purposeful* use of emotional expressions is a central element of communicative socioemotional skills, where individual differences may arise.

Past research on facial expressions produced an abundance of scientific studies that utilized a static viewpoint on faces. Furthermore, these studies mainly used expression recognition paradigms to study the nature and function of facial expressions. Marking the onset of a new research epoch, a series of contributions to a recent special section published in *Emotion Review* 2013 emphasized (1) the need for a theoretical model to explain the expression *production* mechanism and formulated (2) a desideratum for considering the dynamics of facial expression production (e.g., Fernández-Dols, 2013; Scherer et al., 2013).

Basic emotion theories (e.g., Ekman, 1972) that dominated facial expression research in the past postulated prototypical emotion-specific response configurations in the face as a consequence of a particular emotional experience of the person. Within this theoretical framework it has been assumed that expressions originate from so-called affect programs (AP). Importantly, the AP view considered affect display configurations to arise at a discrete time point, and it assumes possibly no differences in the activation timing of action units (AUs, functionally independent facial muscles coded in the Facial Action Coding System (FACS), see below for details).

In contrast, the componential theoretical view on expression production, recently described by Scherer et al. (2013), proposed that facial AUs or AU configurations emerge as a consequence of appraisal results. This perspective considers the production of facial expressions to be a dynamic process so that predictions regarding the sequential appearance of AUs in response to appraisal checks can be made. For instance, if *novelty* is attributed to a stimulus in the context of the appraisal domain *relevance* and the stimulus is further characterized by its sudden appearance, presumably AUs 1 + 2 and 5 will be activated, a configuration that is typically considered to represent fear. In other instances – depending on person-specific characteristics and situative variables – a variety of anger, joy, or even disgust expressions may appear to be a consequence of the same appraisal checks. Furthermore, if the appraisal check leads to some kind of intrinsic pleasantness, AUs 12 + 25 and 38 may be activated and a joy expression will emerge (examples from Scherer et al., 2013).

Reisenzein et al. (2013) listed additional alternative theories that try to explain the emergence of specific emotion-related facial expression configurations. These include Fridlund's (1994) theory that humans have combined AP, which is supported by research from the behavioral ecology field, Fernández-Dols' (1999) situationist view of emotion expression, Frijda and Tscherkassof's (1997) theory that facial expressions are components of evolutionary action tendencies, Parkinson's (2013) theory that emotional expressions are inherited and learned relational orientations, Russell's (2003) dimensional view, which explains that facial expressions are the bases for pleasure–arousal experiences, and Camras et al. (1997) proposal that facial expressions are coordinative motor structures. The authors concluded that alternative explanations to AP (including the componential view by Scherer et al., 2013) are better suited to account for some of the findings on a generally limited coherence between emotion and facial expressions; however, none of the theories are yet advanced enough to account for a series of available empirical findings (Reisenzein et al., 2013).

The Neural Architecture of Facial Expressions of Emotion

Research regarding the neural architecture of facial expression production is still in its infancy (Korb and Sander, 2009; but see Rinn, 1984). Emotional facial expressions are produced by about 20 pairs of facial muscles innervated by the seventh cranial nerve: the facialis originates in the motor nucleus of the facial muscle and is situated in the ventrolateral region of the inferior pons. The existence of two dissociable facial pareses – the emotional versus the voluntary facial paresis (e.g., Hopf et al., 1992) – indicate at least partly different neural networks and mechanisms for spontaneous and voluntary expression production. In addition to patient data, recent neuroimaging studies investigated the functional involvement of brain networks during spontaneous compared with voluntary facial expressions (e.g., Wild et al., 2006). However, artifact problems during PET and fMRI measurement due to facial movements is still an issue and a strong limitation of noninvasive methods.

In a nutshell, these studies suggest that voluntary expressions are controlled mainly by the primary motor cortex (M1) and the lateral premotor cortex (LPMC). These brain areas control the contralateral muscles of the lower face and both contra- and ipsilateral muscles of the upper face, which leads to greater problems in performing asymmetric facial movements with the upper parts of the face, for example the eyebrows. In addition to M1 and LPMC, there are further cortical motor areas involved in facial expressions: the supplementary motor area (M2), and the rostral and caudal cingulate motor area (M3 and M4, respectively; Morecraft et al., 2001). Spontaneous facial expressions, on the other hand, are traditionally believed to be produced by subcortical areas including the basal ganglia and the amygdala; the activity of these areas may be modulated by rostal and medial cortical structures (Rinn, 1984). However, it also seems that emotions may lead to spontaneous facial expressions via the cingulate motor areas (Morecraft et al., 2004).

The facial feedback hypothesis (McIntosh, 1996) assumes that the intentional uptake of an affect display can generate a subjective feeling of the target's affect. Based on this observation, Ekman (1992b) speculated about connections between the motor cortex and additional brain areas involved in emotion processing. The finding that brain regions responsible for affective behavior (e.g., insula, amygdala) are functionally involved during the intentional imitation of emotion expressions and the absence of such activation during chewing and licking in an fMRI setting led Lee and colleagues to conclude that voluntary imitation is interrelated with the affective representation of the emotion (Lee et al., 2006). Due to the sparse knowledge about the neural mechanisms of voluntary versus emotional facial expressions, and the remaining methodological problems inherent in imaging methodologies, we may conclude that the most consistent finding in this area is the involvement of the M1 in the production of voluntary emotion displays whereas its involvement seem to be unnecessary for spontaneous expressions of emotion (Korb and Sander, 2009).

Movements and actions can be studied with a number of neuroscientific methods (beside imaging techniques susceptible

to movements) of which very few have been applied to facial expressions. Individual differences in such measures are not investigated. Scalp-recorded movement-related cortical potentials start about 2 s prior to self-paced voluntary movements (Kornhuber and Deecke, 1965) and include several components: (1) a gradual and bilaterally symmetrical negativity (Bereitschaftspotential: BP); (2) a steeper asymmetrical negativity (negative slope: NS′); (3) a small premotion positivity (PMP); (4) a transient small negative deflection (motor potential: MP); and (5) a large positive deflection (reafferent potential: RAP). The negative slow wave, including the BP and the NS′, is commonly referred to as the readiness potential. As a post-movement component similar to MPs (premovement component), the N+50 (Shibasaki et al., 1980) and frontal peak of motor potential (Tarkka and Hallett, 1991) was reported to have maximal activation over frontal regions, contralateral to the responding limb. These differentiated analyses of movement-related potentials have been measured for finger movements. There seems to be only one study that applied analyses of movement-related event-related brain potentials (ERPs) to voluntary facial expressions: Korb et al. (2008) compared the BP before self-paced unilateral and bilateral smiles with the BP before unilateral finger movements. The BP before bilateral smiles was comparable in size to the BP for right-hand movements (in right-handers) and it showed bilateral symmetry.

The BP is presumably part of a further ERP component, which is elicited when a warning stimulus or cue announces a second stimulus, which requires a response. Usually, negativity with a maximum at the central recording site occurs between the warning stimulus and the response signal. This negative potential has been termed the contingent negative variation (CNV; Walter et al., 1964). When the interstimulus interval is long enough, a first negativity, following the warning signal, can be distinguished from a negativity preceding the response signal. The latter has been related to the BP even if such negativities can be observed also in situations without response requirements. The CNV has been shown to be useful in exploring motor programming. Motor programming refers to the fact that elements of a movement sequence can be prepared in advance of the movement and can be executed without external feedback (Keele, 1968). Very recently, the CNV has been investigated in the context of voluntary facial expressions (Recio et al., 2014). The authors tested the effects of motor planning and reprogramming of facial expressions of happiness and anger and found no evidence for emotion specificity (anger versus joy) in the CNV (initial preparation). However, there was a greater allocation of processing resources for the inhibition of the preactivated motor plan and the updating of a new one in the case of anger compared with happiness expressions.

Individual Differences in the Facial Expression of Emotion

With respect to emotion-related abilities, Scherer (2007) proposed four major areas of competencies where individual differences may occur. The *production* competence refers to the ability of an individual to generate appropriate reactions in emotion-eliciting situations. Among others, the spontaneous expression of emotions in the face falls into this branch of emotion-related competencies. *Response preparation* and *emotion regulation* are further classes of competencies proposed by Scherer. The fourth class of competence, the *communication of emotion*, embraces aspects of productive (encoding) and receptive (decoding) abilities. The voluntary expression of emotion in the face in response to a command can be considered a relevant facet of basic socioemotional communicative abilities. However, the study of the psychometric structure of these abilities, the investigation of their location within a taxonomic model of socioemotional skills, and their relationship to further constructs are still questions that need to be addressed empirically in multivariate studies. Available univariate data, however, can help to postulate psychometric models of facial expressivity.

The structure of individual differences in emotional expressivity has been mainly investigated via self-report measures using structural equation modeling (e.g., Friedman et al., 1980; Gross and John, 1995). Self-report scale scores have then been related to univariate behavioral indicators of facial expressivity. The estimated first-order correlations were, however, zero or of a low magnitude for different self-report scales, ranging between −0.04 and 0.37. Thus, the shared variance between persons' beliefs about their expressivity and their objectively measured expressive skills is maximally 14% (e.g., Gross and John, 1995). Investigating individual differences based on objective measures is therefore a crucial demand for a better understanding of emotion-related production skills in the facial modality.

Individual differences studies applying behavioral observations of spontaneous and voluntary (posed) facial expressions are rather rare and multivariate studies on large samples that allow extracting latent variables that are adjusted for measurement error and method specificity do not exist at all. As far as we know from zero-order correlations of manifest variables, spontaneous and voluntary expressivity in the facial modality are correlated, 0.46–0.62 (Cunningham, 1977; Zuckerman et al., 1976). Thus, there may be a factorial differentiation between spontaneous production of facial expressions and voluntary nonverbal communicative skills. Furthermore, because humans have more or less ample control over their facial expressions, studying the structure of emotional communication skills in the facial modality may even lead to additional difficulties. Measurement paradigms need to include tasks that tap voluntary neutralization, masking, and simulation abilities. The question to be addressed is whether the ability to voluntarily inhibit emotional expressions in emotion-laden situations (neutralization) is distinguishable from the ability to show a different, socially desirable emotion when another emotion is felt (masking), and from the ability to simulate a socially desirable emotion if no emotion is present in a given situation (simulation). Furthermore, emotion category specificity within all these theoretically conceivable ability domains also needs systematic investigations from a latent variable modeling perspective in order to understand individual differences in facial expressivity in a conclusive way.

The Measurement of Facial Expression Production

By classifying observational methods of emotion measurement, Reisenzein et al. (2014) distinguished between (1)

objective behavior coding systems, (2) theory-based observation methods, and (3) intuitive observer judgments of emotions. Whereas the first just codes emotion-related behaviors, the second also makes inferences about emotions based on the coded behavior following some kind of theoretical assumptions. The intuitive observer judgment of emotions relies on an observer's implicit belief about the relationship between different emotions and their behavioral manifestations. All of these types of observational methods have been applied in facial emotion expression research.

The FACS (Ekman and Friesen, 1978) is an objective system for the measurement of facial behavior that is based on anatomical knowledge about the facial muscles and their movement configurations. The FACS codes expressions in terms of AUs that are defined as the smallest possible, functionally independent motions of the facial muscles (for details on coding AUs we refer to Matsumoto, 2009). FACS is an atheoretical coding system of AUs; thus, it does not make any inferences about observable emotion displays based on a particular observed configuration of AUs. Examples of theory-based coding systems are the well-known emotion FACS, which is based on the basic emotion theory and the Facial Expression Coding System (Kring and Sloan, 2007). The FACS system is also used as a component in the Specific Affect Coding System (Coan and Gottman, 2007), which incorporates facial emotion expressions with verbal and other nonverbal behaviors, and tends to code positive and negative emotion constructs (see Reisenzein et al., 2014 for details).

When coding recorded data from behavioral studies on facial expressions of emotion, researchers also adopt observer judgments above objective- and theory-based systems. Such judgments are mainly used for studying individual differences in spontaneous expressivity. For instance, in a slide-viewing paradigm, Buck (1979) asked participants to watch emotionally laden images and to rate their emotional reactions on several emotion scales. During this task, the senders' spontaneous facial expressions were filmed by a hidden camera and presented to receiver participants who were asked, based on the senders' facial expressions, to judge what kind of slide the sender viewed. Generally, the measurement of spontaneous expressivity is based upon induction paradigms using emotional films, pictures, situation descriptions, etc. (e.g., Rottenberg et al., 2007; Harmon-Jones et al., 2007), so that the observed persons are most often unaware that their expressive behavior is recorded (Buck, 1984). In contrast, studies on voluntary expressivity ask participants to do their best at displaying certain expressions or imitating facial emotion displays that are presented.

Recently, we have made attempts to measure individual differences in the ability to express emotion signals in the face using multiple task paradigms. The multiple task approach is essential for assessing abilities. Five experimental tasks were designed asking participants to either produce a specific emotional face, or with varying conditions, imitate a posed facial expression (e.g., static picture or a video). The expressions have been recorded for a period of 5 s, resulting in time series data for a single trial (see **Figure 1**). Before these tasks participants were asked to show a neutral face, in order to assess baseline emotion expression, and before and after the tasks to move specific parts of their face (e.g., raise eyebrows) in order to later assess general facial plasticity. A review of emotion expression coding methodologies suggests that automated software programs (e.g., FACET) are useful for coding numerous images. We compared four scoring methods (arithmetic mean across the 5 s video data, geometric mean, average area under the curve, and max score) as well as four data treatments (untreated, loss smoothing, controlling for baseline facial emotion expression, and controlling for facial plasticity) and found that controlling for baseline facial emotion expression, facial plasticity, and applying a max scoring technique was the best treatment for the data. Controlling for baseline emotion expression accounts for individual differences in base rate emotion expression, which potentially makes some emotions easier for an individual to express compared with others. Controlling for facial plasticity accounts for individual differences in the extent to which one can express particular AUs, thus achieving particular emotion expressions. Finally, during a trial participants may vary in the intensity of their emotion expression; if a score for best performance is desired, the max scoring identifies a participant's highest score and, unlike the other scoring methods, is not affected by that variability (see Figure 1 and Olderbak et al., 2013 for more details).

Toward a Psychometric Model Representing the Structure of the Voluntary Facial Expression Production Ability

It is challenging to postulate a factorial structure of voluntary facial emotion expression (VfEE) as an aspect of socioemotional communicative skills, because research lacks sufficient knowledge regarding the specificity of individual differences in this domain. This is because no available study on VfEE goes beyond the use of univariate measures, reports of mean performance differences across experimental situations, zero-order correlations between spontaneous versus voluntary expressions, or reports of their manifest relationship with decoding abilities and personality traits. Thus, postulations in this area are mostly based on theoretical assumptions.

Conceptually there may be a difference between the *production* and *imitation* of expressions. Production could be defined as displaying facial expressions in response to a particular emotion label, whereas imitation could be defined as voluntarily mimicking the facial expression of another person. It remains an empirical question whether such a differentiation would influence only the mean performance or also the rank order of persons, thus the correlational structure between production and imitation measures. If the rank order is affected, a single latent expression factor might not sufficiently account for the variability in production and imitation performance (see Panel A of **Figure 2** as compared with Panel B). Regarding performance levels, it is plausible to expect higher expression scores, when imitating prototypical expressions, compared with expression scores when producing a facial expression in response to a label. This hypothesis relies on the assumptions that production reflects a higher amount of idiosyncratic (person-specific) expression characteristics which are also a weaker display of prototypical emotion expressions. Socializations theories (e.g., Halberstadt et al., 2001) would postulate differentiable VfEE factors, because the expressivity

Figure 1 Trial level data from tasks measuring emotion expression ability over a time frame of 5 s.

level of the environment in which a person grew up may influence the persons' production ability, but probably the imitation performance less. Imitation performance may instead be related to facial plasticity and extraversion-related personality traits.

In addition to basic production and imitation factors, it can be theorized that the abilities to neutralize (i.e., suppress), mask, and simulate facial expressions are distinct abilities that may be more dependent on situation-specific knowledge about emotion-related display rules, emotion regulatory competence, as well as agreeableness and emotionality-related personality traits. Not named indicators in Figure 2 may represent performance measures of neutralizing, simulating, and masking facial expressions.

Furthermore, it is important to test whether emotion category specific factors besides the more general factors are needed to explain individual differences in production, imitation, neutralization, masking, and simulation measures, or whether global expressivity factors are sufficient to account for the correlations across such measures (see Panel C of Figure 2 as compared with Panels A and B). Again, theories that explain the development of facial expressivity mainly

Figure 2 Schematic representation of a series of conceivable measurement models on the structure of individual differences in facial expressivity measured with multiple behavioral tasks. Boxes represent measured variables, e.g., average performance across a series of trials of an expression task; directed arrows represent directed effects; thus the models assume latent variables (represented as ellipses) to account for the common variance across manifest variables. Panel A represents a model that assumes a general factor to account for the systematic variance across persons in all measures of facial expressivity; Ha, happiness expression trials; Su, surprise expression trials; Fe, fear expression trials; Sa, sadness expression trials; Di, disgust expression trials; An, anger expression trials; empty indicator boxed represent further conceivable measures of facial expressivity beside production (P) and imitation (I). Panel B displays a model that assumes general expressivity not to be sufficient to explain the common variance across all expressivity indicators and would test whether specific variance due to production vs. imitation competence may enhance the model. Panel C displays a more complex model that assumes specific performance differences between persons depending on which emotion needs to be expressed.

through environmental influences, and theories that stress the role of automatic and voluntary mimicking, would predict discrete emotion-specific factors. Because specific environments have a higher probability of eliciting specific emotional displays for certain emotion categories, individuals may become better at expressing some specific emotions compared to others. This would partly explain differences in the rank order of persons for different expression categories.

On the Relation of Facial Expression Production and Their Reception – Exploring the Nomological Net

So far we have reviewed theoretical assumptions and available univariate data that postulate expectations concerning the internal structure of individual differences in behavioral measures of emotion expression abilities related to the facial modality. This leads to an additional important question: how are receptive and productive abilities related within a conceivable taxonomic model of emotional abilities? This question is important for deriving a nomological net around facial expressivity measured as a performance-based construct.

Because encoding and decoding facial information are both crucial aspects of social interactions, they can be considered "opposite sides of the same coin" (Elfenbein and Eisenkraft, 2010, p. 301). Theories and empirical data on their relationship are, however, equivocal, with positive, zero, and negative correlations postulated and reported. Elfenbein and Eisenkraft (2010) summarized the literature that addressed this question and conducted a meta-analysis in the hope to solve the old mystery of the threefold empirical finding. Here, we will briefly summarize these theoretical perspectives and outline the results of the meta-analysis thereafter.

Performance-based emotional intelligence theories and Scherer's theory on emotional competence (Scherer, 2007) postulate a positive relationship between receptive and productive abilities as part of a broader socioemotional communication factor. Furthermore, potential reinforcement might occur between the two sets of abilities. Thus, some individuals may become more expressive because they show stronger mimicking of their counterparts with whom they empathize. Due to their more pronounced empathy, compared to other individuals, they are also better at recognizing emotional displays of others, which is a prerequisite of explicit mimicry (e.g., Osgood, 1966). The theory of emotional contagion also postulates a similar mechanism of reciprocal feedback. Hatfield et al. (2011) reviewed the literature on emotional contagion suggesting that persons tend to automatically mimic the expressions of their counterparts and thereby empathize with the emotions of others, which has the consequence of a better emotion expression recognition triggered by the feedback provided by self-experience due to mimicry. This theory suggests that stronger mimicry behavior leads to more pronounced expressivity that facilitates emotion recognition.

Neurological and psychiatric patient studies of right-brain damaged, Parkinson, schizophrenic, or unipolar depressive individuals also suggest a double dissociation between receptive and productive emotion communication abilities in the facial and vocal modality, as compared with normal controls (e.g., Borod et al., 1990). Halberstadt et al. (2001) advanced a developmental theory of affective social competence that, similarly to Scherer's theory (Scherer, 2007), postulates three dynamically interacting aspects of sending, receiving, and experiencing affect. The authors discuss three developmental disorders characterized by impaired emotional competencies (autism, behavior disorder, and children who suffered from maltreatment) that both receptive and productive aspects of affect communication are impaired in all those cases. Such findings on child populations characterized by emotional malfunctioning also seem to support the view that emotion perception and expression are positively related.

One line of explanations postulating a negative relation between receptive and productive aspects of affective communication emerged from socialization theories advanced earlier by Halberstadt (1986), who argued that children growing up in environments that are low in expressiveness develop a high sensitivity for recognizing affect, even in very subtle displays of emotion, and vice versa. This explanation is embedded into more general theories describing psychological compensation processes across skills (e.g., Salthouse, 1995) and in person–environment interactions. Another line of explanation has been advanced by Zuckerman et al. (1976) who found negative correlations between encoding and decoding, but only for affect displays of different emotion categories, and positive correlations within the same affect class. The authors attempted to explain the negative correlations through mechanisms of interpersonal accommodation, postulating that persons having troubles with perceiving a given affect would assume that other persons face the same difficulty and would seek to express that affect more clearly to facilitate its decoding by their counterparts.

Likewise, Elfenbein and Eisenkraft (2010) advanced possible explanations for a zero correlation between encoding and decoding abilities. They proposed that individual differences in the ability to compensate for family environments might moderate the relationship between encoding and decoding; thus, good compensators may show a negative relationship and those who are less susceptible to compensation would show a positive encoding–decoding correlation. Treating those individuals as one group results in an apparent zero relationship. Furthermore, they listed neurobiological findings suggesting separate brain locations for perceiving and expressing affect. However, there are at least two shortcomings to the brain-behavior explanations. First, the neural networks involved in emotional facial expression seem to partly overlap with brain regions involved in the perception of affect, and second, the neural locations of expressive behavior are still less understood.

In their meta-analysis based on 40 primary studies, Elfenbein and Eisenkraft (2010) explicitly distinguished results for posed versus elicited expressions. They defined elicited spontaneous expressions as being caused by feelings and physiology and posed expressions as being produced through the social intention to communicate states. Overall, the analyses yielded a positive correlation for posed emotion expressions and affect recognition of 0.19 (on the basis of 24 available studies), but no relationship for spontaneous expressions.

However, this positive correlation, which suggests a possible relation between VfEE and decoding abilities, may be

an underestimate due to methodological shortcomings of the available primary studies at the time. These are as follows: the single-task approach used to measure both receptive and productive abilities, the inclusion of a series of neurological and psychiatric patient samples, possibly associated with ceiling effects in recognition tasks for normal controls, and no control for face plasticity and facial expression bias at parameterizing expressive abilities. We argue that a multivariate approach and a more sophisticated modeling of both abilities in a latent variable framework that accounts for task specificity and measurement error will be beneficial to determine the relationship of individual differences between VfEE and decoding abilities by disattenuating it.

Conclusions

Empirical research to date suggests that studying facial emotion expressions is a fruitful line of research for assessing emotion-related abilities. Existing studies suggest the measurement of facial expressions is feasible; however, given the paucity of adequate study designs and measurement tools, much research is needed on this topic. Research produced thus far, however, suggest there are many promising perspectives for this field, including the applied ones. Future research should explore the relation between explicit facial emotion expression and incidential facial mimicry, in addition to their relations with similar constructs. Likewise, facial emotion expression ability and related socioemotional competencies may be deficient in individuals with particular mental disorders (e.g., autism, psychopathy), suggesting these populations provide a unique opportunity to study individual differences in facial emotion expression. Finally, given the importance of expressing emotions facially in everyday communication, and the importance of first impressions in numerous situations (e.g., interviews), research should explore options for training individuals to do better in facial emotion expression, such as producing more intense expressions, or more situationally appropriate expressions.

Abstract

In this article, we summarize popular theories of face identity and facial expression processing. Next, we present some general findings on individual differences in this field including considerations regarding more common and specific face identity and facial expression processing assessment principles. We then discuss available measures and present a task-taxonomy, followed by a short summary of key findings in the field. We then present a summary of research results concerning neural underpinnings in identity and emotion processing. Finally, we conclude with some remarks about the emerging field of identity and expression investigations and some research heuristics.

Faces provide indispensable information for human communication. They inform the perceiver about the familiarity and identity of others and about those persons' emotional states and intentions. The mechanisms of facial information processing and the respective neural correlates received wide attention in the last years. Most of this research is based on experimental findings in healthy participants and evidence from persons with innate or acquired disorders of face processing. This article will focus on variability in these abilities across persons and the structure of individual differences in facial information processing, after providing a summary of theories built upon experimental and clinical research.

Theories of Face Identity and Facial Expression Processing

Functional models of facial information processing (e.g., Haxby et al., 2000; Young and Bruce, 2011) postulate a hierarchical structure, including view-centered pictorial and view-independent structural encoding of the face, access to stored representations of known faces in memory, and to associated (biographical) knowledge about the person and his or her name. In addition to identity processing, these models allow predictions about how the face processing system deals with variable information provided by faces – in particular, emotional expressions, facial movements accompanying speech, and gaze direction. Further, socially relevant information that can be derived from the invariant face structure independent of the person's identity – i.e., age, gender, and judgments about attractiveness – is mapped in these models as visually derived semantic codes. Early theorizing assumed independent streams of identity versus expression-related information. This initial idea was recently modified in favor of partial dependence views (e.g., Calder, 2011; Young and Bruce, 2011). However, it is not yet fully clarified how these systems interact.

Research on the general physiological implementation of face-based processes distinguishes between a core system and an extended system (Haxby et al., 2000). The core system consists of three bilateral, hierarchically organized brain regions. During initial stages of face perception, facial features are processed in the inferior occipital gyri. The inferior occipital gyri provide input to the lateral fusiform gyrus, where invariant aspects of faces – arguably cues of unique identities – are processed. This region has been found to respond more strongly to the perception of faces than to the perception of nonface objects (Kanwisher, 2000). Based on this and similar findings, the so-called fusiform face area (FFA), situated in the fusiform gyrus, has been postulated to be a specialized module for face perception. If attention is directed to changeable aspects of faces, like emotion expression or lip movement, the superior temporal sulci are activated. Visually derived semantic codes, biographical, and name information are processed in the extended system (Haxby et al., 2000). Beyond the core system, an extended neural system – specialized on different cognitive functions – is considered to interact with face-responsive regions (Haxby et al., 2000). We highlight four such systems. First, the intraparietal sulcus is considered to be in charge of processing spatially directed attention and thought to aid the perception of eye gaze direction. Second, the audiovisual integration in speech perception (see the McGurk effect), which is supported by the interplay of the auditory and superior temporal cortex. Third, during emotion processing the superior temporal sulcus maintains connections with the amygdala, insula, and limbic system, which are the neural systems involved in the processing of emotion. Fourth, access to semantic and biographical information during face processing appears to be mediated by anterior temporal regions. Taken together, face processing is supported by multiple brain regions that are spatially disparate, yet act together in a coordinated way. The mechanisms of facial information processing are supposed to be hierarchically organized and actual models assume an interplay between the identity and expression processing routes. Furthermore, Haxby et al. (2000) emphasize that brain systems for facial information processing do not work in isolation but contribute to other cognitive functions such as object recognition.

Individual Differences in Face Identity and Expression Processing

Neurocognitive theories of face identity and facial expression processing describe general mechanisms and the functional organization of the facial information processing system. The

 http://dx.doi.org/10.1016/B978-0-08-097086-8.25060-5

taxonomy, stability, and predictive validity of individual differences in these cognitive mechanisms have been rather recently – at least partly – addressed as a set of independent research questions.

Given the neuroanatomic evidence on at least partly distinct brain localizations of core aspects of face identity and facial expression processing one might be tempted to infer that the abilities to process neutral and emotional faces are highly distinct and independent. However, all of the proposed tasks for measuring facial information processing have attributes of prototypical ability tests: Participants are willing to do their best, there is an objective correct response, and performance is assessed as degree to which responses are correct. It is well known that any two such measures will covary positively in unselected samples – a phenomenon labeled positive manifold in ability research. Therefore, it is unrealistic to expect that (1) measures of face perception that capture individual differences will be completely independent of general cognitive abilities measures and (2) measures of facial emotion processing will be orthogonal to measures of face identity processing. Additionally, when taking a closer look at emotion recognition tasks Adolphs (2002) concluded that emotion identification may be carried out as a combination of processes reflecting perception, semantic knowledge, and reasoning. The independence and redundance of performance in a variety of measures is best investigated by studying their factorial structure.

How do we understand the emotional states of others? Lipps (1907) suggested that persons imitate (mimic) observed affective behavior and that this mimicry elicits a corresponding state in the observer, facilitating or enabling affect understanding. This idea is echoed in modern embodied simulation theories. Indeed, facial mimicry of emotional expressions is frequently observed, although in some cases only with the aid of electromyographic recordings. Mimicry reactions are often involuntary, automatic, and occur within a fraction of a second (Dimberg et al., 2000). The idea that simulation is fundamental for the perception of emotions in others is in line with findings that hindering incidental mimicry leads to performance impairment in emotion perception (e.g., Neal and Chartrand, 2011). However, whether persons who show more incidental mimicry are also better emotion perceivers and whether they do so in all situations is less clear. Hess and colleagues did not observe such a relationship between mimicry and emotion perception in young adults (e.g., Hess and Blairy, 2001). Therefore, facial mimicry may not be necessary for the classification of prototypical emotional displays but may be helpful for social binding or when emotion recognition is difficult. In line with the latter view, Künecke et al. (2014), using a multivariate approach, showed a positive relationship between the degree of facial corrugator response and the ability of emotion perception.

In the popular four-branch theory of emotional abilities, face-based emotion processing is included as one of the key components of emotional intelligence (Mayer et al., 2008). In the component process models (Scherer, 2007) face-based emotion processing is included as receptive decoding. Wilhelm and colleagues (2010) claimed that face identity perception and recognition are core aspects of such emotional abilities. If emotional intelligence exists (Borsboom et al., 2004) individual differences in perceiving neutral and emotional faces ought to be considered lower order factors in a higher order model of socioemotional abilities. Based upon the process theories delineated in the introduction facial information-related decoding abilities may be further subdivided into perceptual and mnestic aspects of performance. Additionally, it is not yet settled whether or not the perception of neutral and emotional faces needs to be distinguished on an individual differences level. Importantly, broader theories of socioemotional abilities that postulate a series of emotion receptive performance components ought to include more or less specific abilities of processing identity and emotion in the voice, gestures, and postures. Obviously, systematically deriving ability measures of such components that are grounded in basic research and incorporating them into factor models of socioemotional abilities is a major challenge for future research.

Apart from distinguishing perceptual and mnestic demands of tasks challenging either identity or expression processing of faces, there is one more crucial task attribute requiring consideration: whether performance is expressed as speed or accuracy. In experimental research many of the tasks used to provoke face identity and facial expression processing are easy to solve. Comparisons between experimental conditions are then usually based on the latency of responses. Within ability research such measures would be considered processing speed tasks because participants from the application population solve a very high proportion of trials correctly and individual differences are primarily manifest in the response latency. It is important to note that easy tasks and hard tasks usually load on different ability factors. Latency-related ability factors may or may not arise as a function of the information content. Indeed, measures challenging the speed of object processing are essentially perfectly collinear with measures challenging the speed of face identity and facial expression processing (Hildebrandt et al., 2012, 2013). This is not true for measures of face identity and facial expression processing scored by the accuracy of responses (Wilhelm et al., 2010). Given the distinction between speed and accuracy tasks that is well established in ability research and the high collinearity of speed-related abilities that lack facets of identity or emotion processing, we recommend avoiding measures of face identity and facial expression processing exclusively challenging the speed of performance.

After narrowing down the face identity and expression processing ability domains based on well-funded experimental research, it is instrumental to consider prior work on socioemotional abilities from other fields of individual differences research. The so-called jingle fallacy refers to instances in which constructs are deemed the same, although they only share a similar verbal label. Conversely, the jangle fallacy refers to instances in which constructs are deemed different although the only obvious distinction is the verbal label established within a scientific community. The recently popularized *theory of mind* and measures arguably capturing individual differences in this ability are probably an instance of a jangle fallacy. The *Reading the Mind in the Eyes* Test displays photographs of the eye region of 36 actors and actresses. Participants are to select which of several response options best matches what those persons think or feel. Obviously, the stimuli and the task presented here are akin

to provoking facial expression processing. It is therefore important to solidly clarify the status of individual differences in such *theory of mind* tasks. Presupposing adequate psychometric characteristics of the measures, we would predict very high correlations between theory of mind and emotion identification (i.e., a jangle fallacy). In that case, the theory of mind ability may not need distinct theorizing.

Measures of Face Identity and Facial Expression Processing

One way to investigate the status quo of individual differences research in this area is to go through available ability measures and search for tasks that use faces as stimuli. We will describe a few such measures – beginning with tasks challenging identity processing and proceeding to measures of facial expression processing – and highlight their positive and negative attributes. It is important to note that we restrict the presentation here to protypical ability measures; meaning the behavior of participants is assessed by comparing responses to an objective standard of performance.

In the famous faces test, participants are asked to pick the correct name out of a few alternatives for each famous face shown. As a measure of identity recognition, this type of test is conceptually problematic because it neglects differences between persons in prior exposure to the face stimuli and knowledge about the displayed famous persons. In the Warrington Recognition Memory for Faces Test no control concerning stimulus attributes irrelevant for face cognition, like clothing, hair, or paraphernalia such as glasses, is applied. Therefore, these irrelevant stimulus attributes might be used to solve the task. Presumably, this is specifically true for participants with severe problems in processing faces, such as prosopagnosic patients. In the Benton Facial Recognition Test, participants are presented a target photo and are asked to select the target identity from six simultaneously presented response alternatives. In some items participants need to identify an identical picture, in others they have to pick the correct identity when pictures are taken from different angles or in different lighting conditions. Although stimulus control is much better here, participants can (and do) still rely on eyebrows and hair lines in processing faces. The objections raised above also apply to most of the available measures of socioemotional abilities and learning and recognition of face-tasks included in many intelligence and memory test batteries. Additionally, in many of these tasks components unrelated to identity and expression processing contribute to performance.

In order to solve issues with face external stimulus components, Duchaine and Nakayama (2006) developed the Cambridge Face Perception Task (CFPT) and the Cambridge Face Memory Test (CFMT). These tests include only face internal features and the perception task successfully minimizes mnestic demands. The CFPT applies morphing: the creation of new faces through blending two different faces into each other. Target faces are morphed with several other faces varying the similarity of the morphed faces with the target face. The target face is presented along with the morphs and participants are asked to order the morphs according to their similarity with the target face. In the CFMT, participants are asked to learn and – after a very brief retention interval – recognize pictures of six faces in different conditions (identical, different angles, different lighting, and degraded through visual noise). Both of the Cambridge tests are certainly superior to many earlier measures.

Despite this somewhat mixed assessment concerning ability tasks relying on neutral faces as stimuli, recent developments in the field are encouraging. On the one side, we recently presented a task battery that allows measuring individual differences in perceiving and recognizing neutral faces and were able to establish and replicate the distinction of these abilities from object recognition and established ability factors (Wilhelm et al., 2010). Within the task battery, an additional aim was to distinguish between tasks challenging either speed or accuracy of processing – a prominent distinction in intelligence research outlined above (Carroll, 1993). The multitask approach for measuring face identity processing-related abilities presented by Wilhelm et al. (2010) includes task paradigms widely used in experimental research on face processing (Part–Whole, Composite Faces, and the Inversion paradigms), different memory paradigms (delayed nonmatching, immediate recall, delayed recall, implicit memory), and over 500 face identities across all tasks. The factorial structure of the tests has been established across a series of independent samples.

With respect to facial expression processing, many measures have an intrinsic component of perceptual speed because stimulus exposition is limited in time (i.e., Japanese and Caucasian Brief Affective Recognition Test (Matsumoto et al., 2000)). The popular Diagnostic Analysis of Nonverbal Accuracy (DANVA; Nowicki and Carton, 1993), which challenges recognition of happiness, sadness, anger, and fear in emotional faces, also has a strictly time-limited stimulus exposition. The manipulations of expression intensity in the DANVA would probably allow the derivation of accuracy scores to express performance. However, the tasks have not yet been probed as measures of accuracy.

The *Profile of Nonverbal Sensitivity* (Rosenthal et al., 1979) is another popular measure, which uses recordings of faces, voices, and bodies as stimuli to assess emotion recognition from multimodal and dynamic stimuli. The use of dynamic facial stimuli is an interesting aspect of the measure but an important drawback here is the limitation to only two emotion categories (positive versus negative).

One out of several measures designed for the assessment of potential disorders of affect processing is the *Florida Affect Battery* (Bowers et al., 1999), which uses static facial, vocal, and cross-modal stimuli and multiple methods (discrimination, naming, selection, and matching). This test is arguably too easy for unimpaired subjects.

The *Multimodal Emotion Recognition Test* relies on 10 categories of emotion expressions but the measure is limited to affect naming as a single observational method. The *Geneva Emotion Recognition Test* (Schlegel et al., 2014) features dynamic and multimodal actor portrayals of 14 emotions – amusement, anger, disgust, despair, pride, anxiety, interest, irritation, joy, fear, pleasure, relief, surprise, and sadness – but exclusively relies on affect naming.

Two tasks challenging perceptual matching and explicit labeling of expression with satisfying psychometric background were recently presented (Palermo et al., 2013). Both tasks build upon the six basic emotions (anger, disgust, fear, happiness, sadness, and surprise). The first task applies an odd-man-out paradigm (i.e., participants have to indicate which out of three simultaneously presented pictures displays a different emotion). The second task requires participants to explicitly identify the emotion in a target face by selecting one of six written labels.

The validity and utility of highly specific information processing paradigms like the *Emotional Stroop Test*, for example, (Matthews et al., 2003) is still unclear.

Most of the above approaches do not allow abstracting from task-specific variance – a crucial step toward studying latent variables (ability estimates) rather than manifest raw scores. Unfortunately, multivariate approaches are more often an exception than the rule in the field. Additionally, stimulus sampling seems to be particularly relevant when creating items and compiling tests (Judd et al., 2012). Very recently Wilhelm et al. (2014) proposed a task battery for measuring facial expression perception and recognition. The same distinction of speed versus accuracy-based measures for face identity processing has also been implemented for the expression processing tasks. The battery includes five tasks for measuring facial expression perception and identification that are based on the composite paradigm, the face inversion paradigm, a measure of emotion discrimination in morphed continua between facial expressions that share action units, and a visual search paradigm with emotional expressions of different intensity. The battery also includes recognition measures that successfully avoid confusing identity and emotion processing and applies different pictures in the learning versus recognition stages. In order to avoid biases arising through applying the same methods for performance assessment repeatedly, multivariate achievement tests should vary memory cues, viewing angles, expression intensity, and the like.

Summary of Key Findings

Theories of face-based receptive communicative abilities – as reviewed above – are mainly originating from the cognitive-experimental literature and were investigated primarily with experimental, neurophysiological, and neurobiological data. However, the structure and predictive validity of mental functions such as face perception, face memory, emotion perception, and emotion memory can only be determined by studying individual differences in a variety of adequate tasks. Overarching theories based on such data – for example, the four-branch theory of emotional intelligence (e.g., Mayer et al., 2008) – are conceptually and theoretically controversial, mainly because their grounding in more basic science is insufficient. Based on the theoretical distinctions and models reviewed above, we postulate a taxonomic model of individual differences in facial information processing that is – arguably – supported by available data.

Following the well-established distinction in the field, a first differentiation of emotional abilities is between receptive (decoding) and productive (encoding) performance. A second critical distinction is between speed performance (i.e., latencies of correct responses) and the accuracy of performance (i.e., proportion of correct responses in tasks that are so hard that some participants cannot solve them regardless of how much time is available). A third important categorization refers to predominant perceptual or mnestic demands of tasks.

Several larger studies critically test these distinctions. For example, based on two larger studies Wilhelm et al. (2010) provided evidence for three factors of face cognition: (1) the accuracy of face perception, (2) the accuracy of face memory, and (3) the speed of perceiving and recognizing unfamiliar faces. These factors were replicated in an independent sample of younger adults with new identities as face stimuli (Hildebrandt et al., 2013). These studies show a clear distinction between speed and accuracy factors, which were nearly completely independent of each other. The shared variance between the performance accuracy and speed of face cognition was less than 5%. This finding has a strong implication for theories and research on face processing, because it shows that research outcomes can tell completely different stories, depending on whether speed or accuracy is analyzed. Additionally, these studies show unequivocally that perception of and memory for faces are distinguishable abilities on the basis of accuracy indicators, but not on the basis of speed indicators. The expectation of a distinction between perception and memory was based on the assumption stressed in face processing models, that at a perceptual stage structural encoding of faces is central, whereas at a memory stage, the access to face representations stored in memory is critical. Obviously, memory performance will partly depend on successful perception. Interestingly, such a perception versus memory differentiation is not feasible on the basis of speed data. Individual differences in the swiftness of recognizing well-learned faces are perfectly collinear with face perception speed. In order to further clarify the status of the speed factor of face cognition, the convergent validity of this factor was studied. On the level of latent variables the speed of face cognition was not distinct from the speed of processing facial emotional expressions and both facial speed factors could not be distinguished from the speed of object cognition. Therefore, the swiftness of performance in these three domains has zero specificity (Hildebrandt et al., 2013).

With respect to the two factors that describe and explain performance in the perception and memory accuracy tasks there is strong and replicated evidence that they need to be dissociated from general cognition, object cognition, immediate and delayed memory for words, numbers and figures, and mental speed. In several samples of young adults, a large amount of variance that is specific for the face cognition factors was replicated. In the first of these studies there was 46% face perception specific variability and 52% face memory specific variability. In an additional study (Hildebrandt et al., 2011), covering an age range from 18 to 88 years, there was no moderator effect of age on the relationship between face perception and face memory versus general cognition, memory, and mental speed. Therefore, this study shows the absence of aging-related dedifferentiation between face cognition on one side and several factors of general cognitive functioning on the other side. Thus, the specificity of face cognition did

not diminish across adult age, despite the expected substantial age-related performance declines. Taken together these results support the assumption that individual differences in face cognition constitute abilities with substantial uniqueness across the adult range.

Conceptually, face perception and face memory can be considered necessary but not sufficient for emotion perception (identification) and memory for emotional expressions. Their empirical distinctness is an essential question to be addressed. Contemporary neurocognitive models of face processing describe partial overlap between the identity and expression processing routes. Recently, Palermo et al. (2013) established correlational evidence in favor of a common first step of identity and expression processing. A factorial model that approximates models of facial information processing may have a nested structure. A theoretical model is depicted in **Figure 1**. To simulate the hierarchical structure of processing face-related information – differentiated through successive processing stages in neurocognitive models – the model first postulates a general factor of face perception. This general factor captures interindividual variability of face perception tasks and accounts for face perception-related variability in all other indicator tasks measuring face memory and facial emotion processing. Second, to represent a partial overlap of the routes processing face identity versus expression that also holds at later stages, the factorial model includes a broad face memory factor that accounts for variability in all memory tasks. Importantly, this factor is purified from variance due to perceptual processing. Two further more specific factors account for variability due to processing emotion-related information only.

The model (1) implies a partial dependency of emotion processing from identity processing and (2) allows for specificity of emotion processing over and above identity cognition. However, the degree of specificity of emotion processing-related factors partialled for face identity processing-related variance is still an unanswered research question. The postulated model needs to be tested on the basis of accuracy data because speed measures of facial emotion processing and the speed of face cognition are perfectly collinear with speed measures lacking interpersonally relevant content.

Once a nontrivial degree of specificity of emotion processing-related factors is established, the emotion specificity is an important research question. It will be interesting to see how strongly indicators of performance in different emotion categories (happiness, surprise, fear, sadness, disgust, and anger) will be related with each other. Although it has been argued that persons may differ in their accuracy to identify specific emotional expressions, because persons may be predominantly faced with different affects during early socialization (e.g., Tomkins and McCarter, 1964), first evidence suggests a lack of emotion category specificity of individual differences (Schlegel et al., 2014). Multivariate research designs will be able to provide more conclusive evidence concerning this question.

Neural Underpinnings of Individual Difference in Face Cognition

The neural mechanisms underlying individual differences in face cognition may provide a deeper understanding of why people differ in these abilities. Performance measures used to derive ability factors are end products of the information processing occurring within the neurocognitive system. In contrast, neuroscientific methods can provide information about the success, organization, and timing of intermediate processing steps that lead to the manifest, end products of performance.

Neuroimaging studies on individual differences in face processing-related abilities are surprisingly rare and confined to small samples of usually not more than 30 participants. The responsivity in bilateral anterior temporal poles and right anterior hippocampus correlated positively with self-rated preexperimental familiarity of face stimuli. Rotshtein et al. (2007) reported that the behavioral impact of second-order (configural) information of faces correlated with the activation of bilateral inferior occipital gyrus and right fusiform gyrus. Both studies rely only on small samples. For a mixed group of normal and prosopagnosic participants Furl et al. (2011) reported that better performance in facial identity processing was positively associated (1) with face

Figure 1 Schematic theoretical model of facial identity and emotion processing; ovals represent latent variables and squares depict indicators used to measure the latent variables.

selectivity in fusiform gyri bilaterally and left anterior temporal lobe, (2) with peak face selectivity in the right and left individually defined FFA, and (3) with the size of the right FFA.

Efforts to tap the neurocognitive mechanisms underlying face cognition in large samples using multivariate modeling are currently restricted to the analysis of event-related brain potentials (ERPs). ERPs are complex responses of the brain to discrete events, such as the presentation of a stimulus, and consist of distinct components that can be related to specific cognitive subprocesses. Amplitudes and latencies of ERPs reflect the intensity and the timing of the processes reflected in these components. Therefore, it is of interest whether individual differences in specific ability factors are related to amplitudes and latencies of specific performance-relevant ERPs. Of particular interest here are ERPs that have been related to the putative stages of face processes as postulated in the functional models outlined above.

The occipital P100 is related to the processing of domain-general, low-level stimulus features and is characterized by a positive peak at occipital scalp sites around 75–135 ms; it is thought to be generated in extrastriate visual brain areas. The N170 is characterized by a negative peak at occipitotemporal sites around 150–190 ms, typically larger for faces than for other objects, but still unaffected by the familiarity of faces. Therefore, it is considered to reflect the configural encoding of facial features and their integration into a holistic percept. Various brain areas have been proposed as sources of the electrical N170, including fusiform, lingual, or occipitotemporal gyri. The Early Repetition Effect (ERE) or N250r is usually operationalized as the difference wave between ERPs to primed and unprimed faces in priming tasks; it is most pronounced at temporal-parietal sites around 260–330 m and presumably originates in the fusiform gyrus. The ERE and Late Repetition Effect (LRE) (see below) are more pronounced for familiar as compared to unfamiliar faces and for personally familiar than for famous faces. Hence, the ERE is associated with the activation of structural representations of faces in long-term memory and with the identification of familiar faces (e.g., Schweinberger and Burton, 2011). Finally, the LRE or N400 – also typically observed in priming experiments – has been related to the activation of person-related knowledge in long-term memory (e.g., Schweinberger and Burton, 2011). It is characterized as the difference wave between ERPs to primed and unprimed faces, usually consisting of a parietal positivity between 330 and 500 m. According to the model for familiar face recognition (see above) the neural generators of the LRE are considered to be part of the extended neural system involved in the retrieving of person-related knowledge (i.e., anterior temporal cortex, precuneus, posterior cingulate cortex).

Kaltwasser et al. (2014) investigated how these ERP components are related with face cognition abilities and with general cognitive functioning. All ERP components could be modeled as unidimensional reliable latent variables. Several such experimentally independent ERPs were only moderately correlated, suggesting that they ought to be considered indicators of specific, essentially independent neurocognitive processes. Shorter latencies of the N170 component along with shorter latencies and larger amplitudes of the ERE and LRE for learned faces have been associated with better face cognition performance. The amplitude of the ERE for learned faces was the strongest predictor of face cognition. The behavior versus ERP latency associations were not face specific, because they diminished after partialing general cognitive functioning.

A few studies investigated the neural underpinnings of individual differences in emotional facial expressions. Kim et al. (2003) reported that more intense subjective experience of surprise is correlated with stronger amygdala activation as measured in fMRI. Using an extreme group design Corden et al. (2006) found less activation of amygdala, fusiform, and anterior temporal cortex in response to neutral faces for participants scoring low on a fear recognition task as compared to a group with normal scores in this task. An ERP study by Tamamiya and Hiraki (2013) found that N170 amplitude predicted the recognition accuracy of happy and angry faces.

Conclusions

Research on face identity and facial expression processing is a rapidly moving field with exciting new developments in many areas. These developments include elaborations on neurocognitive models into the more applied field of individual differences. One consequence of this elaboration is that more and better measurement instruments will be available for research purposes and applied assessment. Research results emerging from this field also have the potential to dramatically improve our current concepts of socioemotional abilities. In opposition to ex-cathedra ideas about the status and organization of socioemotional abilities, an approach grounded in neurocognitive work on identity and emotion processing is obviously a more solid foundation of psychological research. Based upon such a foundation, a variety of intriguing research questions can be proposed. Some of these questions concerning face identity and facial expression processing not addressed in the present contribution include behavior genetics, molecular genetics, sex differences, relevance for a variety of mental disorders, developmental trajectories in childhood, youth, and aging, training and interventions based upon identities and expressions, and many more. Research in all of these areas hinges upon adequate measurement instruments. Due to the relevance of these instruments, we would like to conclude with statements that might seem evident, obvious, and somewhat boring but nevertheless have not been adhered to sufficiently in the past.

The unfolding individual differences research agenda in the field of face identity and facial expression processing is best advised to adhere to the following simple heuristics: Human abilities should be measured with ability indicators. Self-report measures are not ability indicators. Therefore, self-report measures should not be used to study socioemotional abilities. Theoretical claims about abilities should be based on evidence that shows adequate coherence and dependability within measures. Several such measures designed to capture the same ability should show coherence and dependability across measures. Once combinations of established abilities are partialed from such a set of measures a nontrivial amount of residual variance should be present.

This residual variance should predict criteria or outcomes of relevance. The presently available evidence summarized in this contribution endorses the idea that some of the proposed socioemotional ability factors are distinct from established ability factors. This is no small achievement given the fate of many initially intriguing but soon abandoned ideas brought forward in ability research.

Factionalism

Abstract

Factionalism refers to competition between coalitions or groups – factions - within a larger organization or community. Factions compete for resources which provide power chances, such as economic assets, office, honor, ideology and behavioral norms. Since unity and consensus are widely held organizational and community ideals, factions are generally perceived as self-interested and disruptive and members condemned as disloyal. The central focus of a faction is the leader, who has recruited its members. Ties between leader and followers are usually personal, although followers may recruit others on behalf of their leader. Anthropologists first examined factionalism as a structural phenomenon in the late 1950s. It was then perceived as resulting from rapid social change. Factions were regarded as symmetrically organized conflict groups in dynamic equilibrium, a fundamental tenet of functionalism. During the 1970s, reflecting theoretical developments, belief in dynamic equilibrium was gradually abandoned. Competing factions came to be seen as asymmetrical, sometimes manifesting class or ethnic bias and differing in access to resources and strategy, tactics, internal organization and ideology. Factions that persist over time may evolve into corporate groups. Factionalism takes many forms and has been observed in all parts of the world. It occurs in most organizations and communities. It is an intrinsic part of political life.

Factionalism refers to dissension between rival subgroups – factions – within a larger social unit. Factionalism can take many forms and has been observed in all parts of the world. It is a basic political process dynamically related to social change.

Factions and Organizations

Factionalism, regardless of where it is classified on the conflict continuum, is conflict between factions. Factions are coalitions of persons or subgroups that compete over specific issues within a larger organization or community. The central focus of a faction is the leader who coordinates its activities and recruits its members. Ties between leader and followers are usually personal, although some followers may recruit others on behalf of the leader. The issues about which factions compete are diverse. They generally concern scarce resources the control over which provide power chances, such as economic assets, office and new laws. But they may also involve honor, ideology and behavioral norms. Loosely structured, factions are non-corporate groups that generally dissolve when the particular issues that gave rise to them are resolved. But if the issues remain unresolved, factions may acquire a range of cultural trappings such as property, symbols, ideology and bureaucratic organization. They can then evolve into permanent corporate groups, such as ritual moieties, political parties or other formal associations, for which the term faction is no longer appropriate.

Factionalism takes place within the framework of an established social entity, whether village, school, political party, office, club, kin group, etc., that have clear norms of behaviour. These norms generally include notions of unity, consensus, and cooperation.

The covert maneuvering of factions bent on achieving their own, often self-serving aims, contradict these norms. Hence factionalism has a pejorative connotation. It is seen as subverting organizational rules and goals. Faction members are consequently viewed as disloyal, obstructive persons whose pursuit of narrow, short-term advantage endangers the wider, long-term goals of the organization. The divisiveness inherent in factionalism also hampers the day to day affairs of the organization or community that depend on cooperation. Furthermore, factionalism jeopardizes the good name and image of unity and harmony it seeks to project to the outside world.

The Study of Factionalism

The study of factions and factionalism developed slowly, shadowing theoretical shifts in the social sciences. Although Linton (1936) long ago suggested that factions presented an interesting but unexplored field, little was done until the 1950s. Political anthropology until then was dominated by the functionalist paradigm elaborated in *African Political Systems* (Fortes and Evans-Pritchard, 1940). This viewed politics as maintaining order through consensus, harmony, and balanced opposition. The political groups on which functionalists focused were enduring units, corporate groups. Conflict, if examined, was viewed as reinforcing the social structure. Loosely structured, temporary coalitions such as factions patently did fit into this conception of politics. The theoretical hegemony of Africanist political anthropologists began to be challenged in the 1950s. Not surprisingly, Raymond Firth, given his interest in individual choice, had for some time been uncomfortable with the functionalist paradigm. He and colleagues, who had observed factionalism in Indian communities, were the first to examine factionalism theoretically (Firth, 1957). They treated factions as informal counterparts of more formal political formations whose members were recruited according to structurally diverse principles. They also noted that factions tended to become activated on specific occasions and not as regularly recurring features. Other studies of factions and factionalism swiftly

followed (Siegel and Beals, 1960; Boissevain, 1964, 1974; Nicholas, 1965; Bailey, 1969; Thoden van Velzen, 1973; Bujra, 1973; Alavi, 1973). Most employed a transactionalist perspective, viewing political activity as an arena in which entrepreneurs transact personal relations for political and economic gain. The study of factionalism culminated in the late 1970s with the volume edited by Silverman and Salisbury (1977). This is still considered the definitive work on the subject. Following its publication and the demise of functionalist social science – in which trans- actionalists played a significant role – academic debate moved on to puzzles related to symbolic, cognitive, and discursive approaches to politics. Factions and factionalism have become accepted concepts whose characteristics are no longer debated. They are also proving useful to related disciplines (see Brumfiel and Fox, 1994).

Issues

Much of the work on factionalism in the 1960s, although using a transactionalist perspective, continued to be strongly influenced by functionalism. Factionalism was seen as occurring as a result of rapid sociocultural change. Change was seen as coming from the surrounding environment, not as the result of tensions inherent in the community or society in which factionalism arose. Factionalism was generally viewed as occurring because the system's equilibrium was disturbed, and it operated to restore its dynamic equilibrium. Factions were regarded as structurally similar and in balanced opposition. These viewpoints were debated and successfully challenged during the 1970s.

Many of the societies in which factionalism was observed were in fact not subject to rapid social change. But if factionalism was not always a 'result' of change, it seemed always to be 'about' change: changes in power resources, ideology, rules and/or ways of doing things. Factions competed about who was to be boss, about which normative concepts were to be followed, about whose will was to prevail, and thus about which rules were to be followed. Moreover, a closer examination of rival factions revealed that far from being similar or evenly matched, they differed in their access to resources, strategy, tactics, internal organization, ideology, and social composition.

Factions: Structure, Symmetry, and Balance

Factions often form in opposition to or in defense of some issue or some pre-existing source of power and authority within a community or organization. The distribution of such resources is binary. Some persons have more and some have less. Those with more normally constitute the local establishment that coalesces around a leader or a dominant personage such as a headman, mayor, parish priest, or club president. They and their supporters form the 'establishment' faction. Those who are dissatisfied with the establishment's exercise of its power constitute a category from which a rival or 'opposition' faction can be recruited.

Reports also mention conservative and progressive factions. Because the local establishment normally defends the 'status quo,' from which it derives its superordinate position, it is often labeled as conservative. Since the opposition faction challenges the established defenders of the 'status quo' it is labelled progressive. These labels often do not reflect reality, as when a progressive opposition faction defeats its rival and becomes the dominant, establishment faction. There is a further reason why opposition factions come to be regarded as progressive. Since they are weaker, they are perhaps more receptive to new resources if and when these become available in the wider society. With these they can challenge their rivals. In rapidly changing societies these may include new government and commercial offices, new laws and new ideologies. Such new resources rapidly tend to change the balance of power. Factionalism thus does not necessarily result from the availability of new resources, as some authors have suggested. Rather, new resources are used in ongoing competitions for power and prestige and tend to escalate the conflict. The use of new resources is not random. A faction will use new resources when it seems likely that they will strengthen its position. It is then labelled progressive, in the sense of favoring change of the 'status quo.'

There is evidence that conflict groups – whether faction, ritual moiety, or political party – differ organizationally. When the opposition consists merely of a category of persons disgruntled with the dominant power elite, they are obviously less organized than the establishment. The internal structure of the local establishment faction, whose members are used to networking to maintain their position, will normally have a more developed exchange circuit than the opposition faction. But if a conflict between the two persists over time, the opposition faction may well become better organized than its rival may. Good organization is a valuable resource and one of the ways a weaker faction can successfully challenge its rival. It is thus more open than the establishment faction to organizational innovation. Because of its superior resources, the dominant faction also tends to be more wasteful. It does not need to husband its resources to the extent that its weaker rival does.

Like most coalitions, factions have core and peripheral members. Core members cluster around the leader and have multiple links to each other. The peripheral members are often linked only to the leader or to a single member of the core group. Where there is a strong core, the faction often acquires some of the characteristics of corporate groups noted previously.

Factions are not necessarily ideologically neutral, as some authors have suggested. The differences between establishment and opposition, like those between conservative and progressive, are not random. They have ideological implications. There is evidence that opposition factions recruit more support than their rivals from weaker or even marginal social categories do. Since opposition leaders usually lack the network ties and material resources that establishment leaders use to recruit followers, they cannot afford to be too particular about the nature of their support. The strength of a faction is usually a function of its size. Just as they often turn to new ideologies and tactics – which because they are new are often viewed as socially unacceptable and subversive – opposition leaders also recruit supporters from among those who are less influential or are regarded as social or morally inferior. Followers are followers.

Opposition factions consequently often develop or adopt an overarching ideology or symbol to bind their heterogeneous members into a unity. They also often align themselves with political parties that defend the interests of their socially weaker supporters. Most often, opposition factions seek links to parties that embody an emancipatory ideology. Their establishment rivals develop relations with political parties representing vested interests in the wider society. Political parties, on the other hand, also consciously make use of local factions to recruit support at the grass roots level.

Conclusion

If factionalism is not necessarily a product of social change, it appears to be always about change. Factions are coalitions that compete for power to determine, and thus to change, what is to be accepted as normal. Rival factions, because they have different access to power chances, are not evenly matched, structurally similar groups. Their asymmetry is fundamental to understanding the nature of factionalism and its dynamic for long term change.

Structural asymmetry and competition for power are also characteristic of class-based conflict groups. This suggests that the line of cleavage between faction, class or party cuts across moral categories and socioeconomic classes, not at right angles, as most functionalist and class-oriented analysts postulate, but diagonally. Where the line approaches the vertical, forming conflicting coalitions with a generally even spread across socio-economic classes, it is reasonable to speak of factionalism, in the case of face-to-face groups, and party conflict in the case of conflict on a broader scale. Where the line of cleavage approaches the horizontal, forming conflict groups that are more clearly differentiated according to socio-economic criteria, the term class conflict seems appropriate. But in every case the axis of cleavage must be determined by empirical investigation. It should not be taken for granted.

Factor Analysis and Latent Structure Analysis: Confirmatory Factor Analysis

Abstract

Confirmatory factor analysis (CFA) is a quantitative data analysis method that belongs to the family of structural equation modeling (SEM) techniques. CFA allows for the assessment of fit between observed data and an a priori conceptualized, theoretically grounded model that specifies the hypothesized causal relations between latent factors and their observed indicator (manifest) variables. Because population-level equivalence between data and model cannot be shown with sample data, CFA should be viewed as a mainly disconfirmatory technique. That is, CFA facilitates the statistical rejection – or, at best, a tentative retention – of a specific theory regarding the factor(s) responsible for the observed relations in the data. If, on the other hand, the investigator's intentions are a mostly ungrounded exploration of relations suggested by the data, classical exploratory factor analysis is the more appropriate approach. In this article, typical steps in a CFA are introduced theoretically and via example: from model specification and identification, to parameter estimation, data-model fit assessment, and potential model modification. Didactic references are provided for a more in-depth study of CFA and SEM techniques in the social and behavioral sciences.

Overview

The term *factor analysis* describes a host of methods, all of which have the purpose of facilitating a better understanding of the unobserved variables (factors) that underlie a set of directly measurable and observed variables (for a nontechnical overview, see Bandalos and Finney, 2010 and references therein). These factors are often believed to represent constructs, psychological or otherwise, that have a direct bearing on the measured variables; as such, they are assumed to motivate (and in turn be inferable from) the pattern of covariances (unstandardized correlations) among those observed variables. In the late 1960s, works by Karl Jöreskog (e.g., 1966, 1967) articulated a method for *confirmatory factor analysis* (CFA), an application of normal theory maximum likelihood estimation to factor models with specific theoretical latent structures. Such structures could include the a priori specification of the number of factors, their orthogonality or obliquity, and which variables had zero and nonzero relations with those factors. This distinguishes CFA from well-known *exploratory factor analysis* (for classic introductions, see Gorsuch, 1983; Mulaik, 1972) wherein the number and nature of the factors emerge from the observed variables' data through a mathematical algorithm, largely blind to any substantive theory. Most crucial in Jöreskog's CFA work was the provision for a formal statistical χ^2-test of the fit between the pattern of relations among the measured variables and the theorized factor model, thereby facilitating the disconfirmation or tentative confirmation of a hypothesized factor model. Soon after, Jöreskog and others put forth a more general framework for the integration of measured and latent variables into causal networks, serving as the foundation for what is often known as *structural equation modeling* (SEM). CFA, which may be considered a special case within the more general SEM framework, is the focus of the current article.

CFA Model Specification, Identification, and Parameter Estimation

Suppose an educational researcher wishes to investigate the possibility of a low positive relation between reading and mathematics ability for fifth grade students, which is measured by standardized tests such as the Stanford Achievement Test or the Iowa Test of Basic Skills. The model shown in Figure 1 might be hypothesized. Measured variables X_1 through X_6, shown in rectangles, are believed to be caused by the latent factors ξ_1 and ξ_2, shown in ellipses. Here, ξ_1 and ξ_2 represent

Figure 1 Hypothetical CFA model of reading and mathematics ability.

true latent (unobserved) reading and mathematics ability, respectively, with X_1 through X_3 being standardized reading test measures (Read1 through Read3) and X_4 through X_6 being standardized mathematics test measures (Math1 through Math3). Table 1 includes a simulated variance/covariance matrix for the observed variables X_1 through X_6 based on test data from $n = 1200$ fifth graders. Our example's focus is the noncausal covariance between reading and mathematics ability, ϕ_{21}. In SEM path diagrams, a covariance is indicated by a two-headed arrow connecting the two constructs, and – because a variance is a covariance of a variable (observed or latent) with itself – it, too, is depicted by a two-headed arrow, in this case from the variable to itself.

A factor's hypothesized causal impact on its measured indicator variables, its *loading*, is symbolized by an arrow from the factor to the variable with magnitude λ_{ij}, where i denotes the observed variable and j denotes the latent factor. Note that such a model explicitly posits the factors as causing the variables, rather than the variables causing the factors; the latter type of model, in which the factor is characterized as *emergent* rather than *latent*, is much less common and beyond the scope of this article (but see Kline, 2013). In many cases, there is no arrow from a factor to a variable, such as from ξ_1 to X_4; this implies that reading ability has no theoretical causal bearing on the Math1 variable. Finally, to the extent that the factors do not perfectly explain each variable, a residual term, δ_i, is included as an influential contributor (with its variance shown by a two-headed arrow from δ_i to itself). This residual might consist of variable-specific measurement error as well as other influences. Thus, each observed variable is the sum of two parts, that attributable to the latent factor(s) and a residual part unique to the variable.

The causal relations of the hypothesized model shown in Figure 1 may be expressed as a system of six regression-like *structural equations*:

$$X_1 = \lambda_{11}\xi_1 + 0\xi_2 + \delta_1 \quad [1]$$

$$X_2 = \lambda_{21}\xi_1 + 0\xi_2 + \delta_2 \quad [2]$$

$$X_3 = \lambda_{31}\xi_1 + 0\xi_2 + \delta_3 \quad [3]$$

$$X_4 = 0\xi_1 + \lambda_{42}\xi_2 + \delta_4 \quad [4]$$

$$X_5 = 0\xi_1 + \lambda_{52}\xi_2 + \delta_5 \quad [5]$$

$$X_6 = 0\xi_1 + \lambda_{62}\xi_2 + \delta_6 \quad [6]$$

Equivalently, these equations can be represented in matrix form, as in

$$\begin{bmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \\ X_6 \end{bmatrix} = \begin{bmatrix} \lambda_{11} & 0 \\ \lambda_{21} & 0 \\ \lambda_{31} & 0 \\ 0 & \lambda_{42} \\ 0 & \lambda_{52} \\ 0 & \lambda_{62} \end{bmatrix} \begin{bmatrix} \xi_1 \\ \xi_2 \end{bmatrix} + \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \\ \delta_5 \\ \delta_6 \end{bmatrix} \quad [7]$$

That is,

$$\mathbf{X} = \mathbf{\Lambda\xi} + \boldsymbol{\delta} \quad [8]$$

where $\mathbf{X}$ is a column vector of observed variables, Λ is a matrix of factor loadings, $\boldsymbol{\xi}$ is a vector of latent constructs, and $\boldsymbol{\delta}$ is a column vector of residuals.

The implication of Figure 1 and the accompanying structural equations is that the population variance/covariance matrix for the X variables, $\mathbf{\Sigma}$, is a function of (1) the λ_{ij} loadings in matrix Λ, (2) the variances and covariance of the latent factors in a matrix $\mathbf{\Phi}$, and (3) the variances and covariances among the residuals in a matrix $\mathbf{\Theta}_\delta$ (note that in Figure 1 all residual covariances are zero as implied by the absence of two-headed arrows between the δ terms). More specifically, if all model parameters (loadings, variances, and covariances) are contained in a single column vector $\boldsymbol{\theta}$, the population variance/covariance matrix of the observed variables that is implied by the model and its parameters, $\mathbf{\Sigma}(\boldsymbol{\theta})$, is given by

$$\Sigma(\boldsymbol{\theta}) = \mathbf{\Lambda\Phi\Lambda}' + \mathbf{\Theta}_\delta \quad [9]$$

A vector of parameter estimates, $\widehat{\boldsymbol{\theta}}$, can be derived so that the model-implied variance/covariance matrix $\mathbf{\Sigma}(\widehat{\boldsymbol{\theta}})$ is as similar as possible to the observed variance/covariance matrix, $\mathbf{S}$, provided that model identification has first been ensured. To that end, each parameter in a model must be expressible as a function of the variances and covariances of the observed variables. When a system of such relations can be uniquely

Table 1 Simulated data and selected parameter estimates for the reading and mathematics ability model in Figure 1

	X_1	X_2	X_3	X_4	X_5	X_6

$\chi^2 = 16.98$, $df = 8$ $p = 0.030$		CFI = 0.996	SRMR = 0.016		RMSEA = 0.031	

Note. $^*p < 0.05$.

solved for the unknown parameters, the model is *just-identified*. When multiple such expressions exist for one or more parameters, the model is *overidentified* and, in that case, a best-fit (although not unique) estimate for each parameter is derived. If, however, at least one parameter cannot be expressed as a function of the observed variables' variances and covariances, the model is *underidentified*, and some or all parameters cannot be estimated on the basis of the data alone. This underidentification might be the result of the researcher attempting to impose a model that is too complex relative to the number of variances and covariances of the observed variables. Additionally, empirical underidentification might arise when unfortunate estimates for select parameters (e.g., values of zero for factor covariances) render subsets of model parameters inestimable. Fortunately, in most CFA applications, it suffices to ensure that (1) the total number of parameters to be estimated, t, does not exceed the number of unique variances and covariances of the observed variables, u, and (2) each latent factor has an assigned unit of measurement. To accomplish the latter condition for the model in **Figure 1**, we set the factor variances to unity (alternatively, for each of the two factors we could have specified one of the factor loadings to equal unity, thereby setting each factor's units equal to those of the observed variable). The model in **Figure 1** is overidentified with $u = 6(7)/2 = 21$ nonredundant observed variances and covariances and $t = 13$ parameters to be estimated: six factor loadings, one covariance between the two latent factors, and six variances of the residual terms associated with the observed variables.

Given that a model is just- or (preferably) overidentified, sample estimates can be obtained through a variety of estimation methods. These include maximum likelihood and generalized least squares, both of which assume multivariate normality and are asymptotically equivalent, as well as asymptotically distribution-free estimation methods that generally require a substantially larger sample size. These methods iteratively minimize a function of the discrepancy between $\mathbf{S}$ and $\boldsymbol{\Sigma}(\widehat{\boldsymbol{\theta}})$, where $\mathbf{S}$ is the unrestricted variance/covariance matrix of the observed X variables and $\boldsymbol{\Sigma}(\widehat{\boldsymbol{\theta}})$ is the model-implied variance/covariance matrix reproduced from the iteratively changing parameter estimates. The standardized maximum likelihood estimates of key parameters in the reading and mathematics ability model are presented in **Table 1**. Before focusing on the estimate of the example's main parameter of interest (ϕ_{21}), we should consider whether or not there is any evidence suggesting data-model misfit, any statistical – and theoretically justifiable – rationale for modifying the hypothesized model, or any indication of factor unreliability.

Data-Model Fit Assessment and Model Modification

One of the advantages of CFA is the ability to assess the quality of the fit of the data to the model. A multitude of measures exists that assist the researcher in deciding whether to reject or tentatively retain an a priori specified overidentified model (see Marsh et al., 1988; Tanaka, 1993). In general, measures to assess the fit between the variances and covariances observed in the data and those implied by the model can be classified into three categories: absolute, parsimonious, and incremental. *Absolute* fit indices are those that improve as the overall discrepancy between $\mathbf{S}$ and $\boldsymbol{\Sigma}(\widehat{\boldsymbol{\theta}})$ decreases. Examples of such measures include the model χ^2 statistic that tests the stringent null hypothesis H_0: $\boldsymbol{\Sigma} = \Sigma(\boldsymbol{\theta})$, the standardized root mean-square residual (SRMR) that roughly assesses the average standardized discrepancy between observed and model-implied variances and covariances, and the goodness-of-fit index (Jöreskog and Sörbom, 1996) designed to evaluate the amount of observed variance/covariance information that can be accounted for by the model.

Parsimonious fit indices take into account not just the overall absolute fit, but also the degree of model complexity required to achieve that fit. Indices such as the adjusted goodness-of-fit index (Jöreskog and Sörbom, 1996), the Akaike Information Criterion (Akaike, 1974), and the root mean-square error of approximation (RMSEA, Steiger and Lind, 1980) indicate greatest data-model fit when data have reasonable absolute fit and models are relatively simple. Finally, *incremental* fit indices such as the normed fit index (Bentler and Bonett, 1980) and the comparative fit index (CFI, Bentler, 1990) gauge the data-model fit of a hypothesized model relative to that of a more restrictive baseline model with fewer parameters.

The three types of fit indices together help the researcher to converge upon a decision regarding the CFA model's acceptability. In our example, the statistically significant maximum likelihood $\chi^2 = 16.98$ ($df = u - t = 8$, $p < 0.05$) indicates that the observed variance/covariance matrix would occur rarely if our model correctly depicted the true population relations. This absolute fit statistic, however, is notoriously sensitive to very small and theoretically trivial model mis-specifications (e.g., slight amounts of error covariance) under large sample conditions. As such, other fit indices are generally preferred for model evaluation. According to Hu and Bentler (1999), for example, CFI values of 0.96 or greater together with SRMR values less than 0.09 (or with RMSEA values less than 0.06) point to acceptable data-model fit. The indices in **Table 1** suggest no appreciable data-model inconsistency given the Hu and Bentler recommendations.

After the data-model fit has been assessed, a decision about that model's worth must be reached. Acceptable fit indices usually lead to the conclusion that no present evidence exists warranting a rejection of the model or the theory underlying it. This is not to say that the model and theory have been confirmed, much less proven as correct; rather, the current factor model remains as one of possibly many that satisfactorily explain the relations among the observed variables (see Hershberger and Marcoulides, 2013). On the other hand, when fit indices indicate a potential data-model misfit, one might be reluctant to dismiss the model entirely. Instead, attempts are often made to modify the model post hoc so that acceptable fit indices can be obtained. Such modifications could include the addition of cross-loadings, allowing a given variable to load on multiple factors, or of error covariances in which variables' residuals are allowed to covary in order to reflect some potential variable relation above and beyond that motivated by the factor structure itself.

Most CFA software packages will facilitate such model improvement by providing modification indices (Lagrange multiplier tests) indicating what changes in the model could

reap the greatest increase in absolute fit, that is, decrease in the model χ^2 statistic. While such indices constitute a potentially useful tool for remedying incorrectly specified models, it seems imperative to warn against an atheoretical hunt for the model with the best fit. Many alternative models exist that can explain the observed data equally well; hence, attempted modifications must be based on a sound understanding of the specific theory underlying the model. Furthermore, when modifications and reanalyzes of the data are based solely on data-model misfit information, subsequent fit results might be due largely to chance rather than true improvements to the model. Modified structures therefore should be cross-validated with an independent sample whenever possible. If a new sample is not available but the initial sample is large enough, one can randomly split the sample into calibration and validation subsamples and compute Cudeck and Browne's (1983) cross-validation index. When the initial sample is too small, Browne and Cudeck (1989) also offered a single sample alternative, an estimate of the expected value of the cross-validation index. From the analysis of the model in **Figure 1**, none of the modification indices suggested changes to the model that would result in a significant improvement in data-model fit (i.e., a significant decrease in the model χ^2 statistic); thus, we did not report them in **Table 1**.

Before drawing conclusions regarding the relation between reading and mathematics ability, the question of the quality (i.e., reliability) of the factors should be addressed. Traditionally, this has been accomplished (1) by focusing on the reliability of scores from individual indicator variables, R^2 (i.e., the proportion of variability in an observed variable that can be accounted for by the underlying factor), or (2) by assessing the reliability of scores from linear composites of the indicator variables (e.g., Miller, 1995; Raykov, 1997). Alternatively, Hancock and Mueller (2001) suggested a measure (coefficient H) computable most easily from the standardized factor loadings that can be used to assess the reliability (i.e., replicability) of a latent construct itself as reflected by scores from its multiple observed indicator variables. One of coefficient H's advantages over traditional construct reliability measures is that it is never less than the best indicator variable's reliability (R^2), thereby drawing information from all indicators in a manner commensurate with their own ability to reflect the construct. For the current example, $\widehat{H} = 0.79$ and $\widehat{H} = 0.82$ for the reading and mathematics ability constructs, respectively, while the R^2 values for the respective factors' indicator variables in **Table 1** range between 0.49–0.62 and 0.35–0.73. Thus, the two factors exhibit reasonable and satisfactory levels of construct reliability, given that about 80% of their variance is explainable by their respective indicators. **Table 1** also lists the standardized factor loadings, that is, the standardized versions of the λ_{ij} parameters in the $\mathbf{\Lambda}$ matrix that indicate the strength and direction of the a priori specified causal influences of the latent factors on the observed variables. All factor loadings are positive and statistically significantly different from zero ($p < 0.05$).

Finally, our primary research question can be addressed. The CFA estimate of the correlation between the two latent constructs reading and mathematics ability is 0.51 and statistically significantly different from zero ($p < 0.05$). This estimate indicates a low to moderate positive association between the two constructs of interest, as hypothesized.

Conclusion

CFA has become established as an important analytical tool for many areas of the social and behavioral sciences. It belongs to the family of SEM techniques that allow for the investigation of causal relations among latent and observed variables in a priori specified, theory-derived models. The main advantage of CFA lies in its ability to aid researchers in bridging the common gap between theory and observation. For example, an instrument might be developed by creating multiple items for each of several specific theoretical constructs (**Figure 1**). Instead of analyzing data with an exploratory factor analysis (where each item is free to load on each factor) and potentially facing a solution inconsistent with initial theory, a CFA can give the investigator valuable information regarding the fit of the data to the specific, theory-derived measurement model (where items load only on the factors they were designed to measure), and point to the potential weakness of specific items. CFA is best understood as a process, from model conceptualization, identification, and parameter estimation, to data-model fit assessment and potential model modification. As opposed to exploratory methods, CFA's strength lies in its disconfirmatory nature: models or theories can be rejected, but results might also point toward potential modifications to be investigated in subsequent analyses.

A recent treatment of CFA for applied researchers is Brown (2009). Popular textbooks on more general SEM – those that include many CFA examples from disciplines covered in this encyclopedia and that utilize commonly available software (i.e., AMOS, EQS, LISREL, and MPlus) – are Bollen (1989), Byrne (1998, 2006, 2010, 2012), Kline (2011), Loehlin (2004), Raykov and Marcoulides (2006), and Schumacker and Lomax (2010). Social science journals that publish many CFA and SEM applications and methodological developments include *Educational and Psychological Measurement*, *Multivariate Behavioral Research*, *Journal of Experimental Education*, *Psychological Methods*, *Sociological Methodology*, *Sociological Methods and Research*, and *Structural Equation Modeling: A Multidisciplinary Journal*.

Factor Analysis and Latent Structure Analysis: Overview

David J Bartholomew, London School of Economics, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

For over 100 years, factor analysis has probably been the most widely used multivariate technique among social scientists. It is still not well known that it is one of a family of methods which share the same theoretical framework and pose similar problems of interpretation. These are known, collectively, as latent variable methods. The family also includes latent class analysis and latent profile analysis. The family connection is described here within a framework which is designed to show what they have in common. Latent variables play a fundamental role in social science and some other occurrences are briefly touched upon.

Introduction

The terms factor analysis and latent structure analysis refer to two aspects of essentially the same problem. In practice, a 'factor,' as the term is used in factor analysis, is simply a latent variable and the failure to recognize this equivalence has often caused much misunderstanding. In ordinary statistical usage the term 'factor' is used, rather loosely, to refer to almost any variable. The reason for this imprecision is historical in that factor analysis is, possibly, the oldest multivariate statistical method. It was invented by Charles Spearman around 1904, and was developed and initially used almost exclusively by psychologists. It is now possible to see the two strands in their proper relationship.

A latent variable is any variable occurring in a statistical problem, which cannot be observed. This may be because it is inconvenient, or impracticable, to observe it or it cannot be observed, even in principle. The latter case includes what we might call hypothetical variables, which are introduced into a statistical problem because they simplify the interpretation of the results. For example, one of the earliest and most enduring examples of a latent variable is 'general ability.' This is closely related to the subject of Spearman's original work on general intelligence. It is commonly found that scores on tests of arithmetic, for example, made on the same individual, say, are highly correlated with one another. This is usually put down to the fact that all such scores depend on an underlying ability to perform such tests. By introducing a latent variable representing arithmetical ability, the interpretation of the data can be considerably simplified. Sometimes the object of the analysis is less specific and we merely inquire whether there might be any latent variable, which plays such an explanatory role without knowing, in advance, what it is. The problem then is to identify what that latent variable might be in terms which make substantive sense.

Viewed in this way, latent variable analysis is a special case of a much wider range of statistical problems concerning unobserved variables, which has been treated in Bartholomew (2013). These include missing values, simple mixtures, and, when viewed appropriately, time series analysis. Indeed, the whole of statistics is included if we approach the subject from a Bayesian perspective where parameters are treated, in effect, as latent variables.

The Basic Idea

Although factor analysis and other latent variable methods are often regarded as relatively advanced multivariate methods, they all depend on a very simple idea. This idea is very familiar to students, in elementary statistics courses, under the guise of what is called 'spurious' correlation. There it is explained that a correlation between two variables may not be due to a real causal link between them, but be caused by the presence of a third variable which is related to both. This common influence results in a correlation which is properly called 'spurious.' To take an old example where the relationships are now relatively well understood, consider the variables involved in cancer of the lung. It has long been known that the amount of tobacco smoke inhaled by an individual is positively correlated with the risk of cancer of the lung. But it could be argued that this correlation could be spurious because it might be induced by some other variable. For example, living in an urban environment, with its polluted atmosphere, might be the cause of both smoking and lung cancer. Had this been the case, the correlation between smoking and lung cancer would have vanished if the analysis had been done for subgroups whose members all had the same exposure to polluted air. In essence, the general aim is to find other variables which, if held constant, would have eliminated the correlation between smoking and cancer.

In any latent variable analysis the aim is to 'explain' the correlations between observed variables by showing that they could have arisen because of their dependence on other, unobserved, variables.

This idea may be further illustrated by a numerical example using only binary variables called A and B and expressing their relationship in the familiar form of a 2×2 table.

	$A = 1$	$A = 0$	*Total*
$B = 1$	700	400	1100
$B = 0$	300	600	900
Total	1000	1000	2000

This table shows a positive association between A and B; if $A = 1$, B is more likely to be 1 than if $B = 0$. Suppose now there is a third binary variable called C. We might then look at the association between A and B for each of the two values taken by C. Suppose the breakdown gives the following two tables.

$C = 1$	$A = 1$	$A = 0$	*Total*
$B = 1$	640	160	800
$B = 0$	160	40	200
Total	800	200	1000

$C = 0$	$A = 1$	$A = 0$	*Total*
B = 1	60	240	300
B = 0	140	560	700
Total	200	800	1000

It is clear that there is no association between A and B in either of the last two tables; the column frequencies in the first two columns are in exactly the same proportion as in the final column. This implies that the association in the first table is entirely spurious because, when we hold C constant, the association vanishes.

Although this highly simplified example conveys the basic idea, real problems are much more complicated. The variables need not be binary but could be continuous, categorical – with and without ordering of the categories – or any mixture of the two. In our example, there was only one latent variable, C. In practice there may be several and, as with the observed variables, they may be continuous or categorical. In all cases the essential idea is to find whether variables exist, like C, such that, when we condition on them, the observed variables become independent.

We now go over this ground again but this time in greater generality.

Formal Statement of the Conceptual Framework

The last section sets out the key idea underlying all latent variable models. Now, the general approach is expressed more formally in mathematical terms. This is essential if the full generality is to be grasped but, to ease the path of the nonmathematical reader, we treat only the case of continuous variables and simplify the presentation by omitting details such as the limits of integration. Full details will be found in Bartholomew et al. (2011), but the reader who is interested only in specific models may pass immediately to later sections.

Denote the set of observed variables by the p-vector, $\mathbf{x}$. Its elements, $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_p$ may be continuous or categorical or a mixture of the two. These are the generalization of the binary variables A and B of the last section and they are often referred to as 'manifest' variables. The latent variables are similarly denoted by the q-vector, $\mathbf{z}$.

The essential thing about this kind of model is that $\mathbf{z}$ is not observed. For this reason everything must be expressed in terms of the distribution of the observable variables $\mathbf{x}$. The relationship between the two can be obtained by using standard probability methods as

$$f(\mathbf{x}) = \int f(\mathbf{x}, \mathbf{z})\mathrm{d}\mathbf{z} \qquad [1]$$

Here, as already noted, the equation is written as if the variables were all continuous – hence the integral in eqn [1]. This is purely for convenience and the translation needed to cover other cases does not affect the logic of the argument. The next step is to write

$$f(\mathbf{x}, \mathbf{z}) = f(\mathbf{z})f(\mathbf{x}|\mathbf{z}) \qquad [2]$$

This decomposition provides us with the two elements to which the description of the last section referred – namely a statement of how the manifest variables would vary if $\mathbf{z}$ were known, given here by $f(\mathbf{x}|\mathbf{z})$, and the prior distribution of $\mathbf{z}$. If both parts of eqn [2] can be specified, $f(\mathbf{x})$ can be determined and thus the way is open to estimate any parameters of the model from a likelihood function constructed from $f(\mathbf{x})$. To scale $\mathbf{z}$, that is to find a value for $\mathbf{z}$ for an individual with a given $\boldsymbol{x}$, we may use the posterior distribution given by

$$f(\mathbf{z}|\mathbf{x}) = f(\mathbf{z})f(\mathbf{x}|\mathbf{z})/f(\mathbf{x}) \qquad [3]$$

A scale value, or factor score as it is known, for a particular $\mathbf{z}$ can then be found by using some measure of location of its posterior distribution such as $E(\mathbf{z}_i|\mathbf{x})$. This specification is deceptively simple. It merely spells out some of the consequences of regarding $\mathbf{x}$ and $\mathbf{z}$ as random variables. To turn it into a model we have to specify $f(\mathbf{z})$ and $f(\mathbf{x}|\mathbf{z})$. Here we face a fundamental problem because the decomposition of eqn [3] is not unique – there are infinitely many possible pairs, each leading to the same $f(\mathbf{x})$ and hence indistinguishable empirically from one another.

The choice of $f(\mathbf{z})$ is resolved by appealing to the fact established above that, since $\mathbf{z}$ is a latent variable, it can be constructed to have any convenient distribution. For instance, as a matter of convention one may choose the $\mathbf{z}$'s to be standard, normal, and mutually independent.

The core of the model-building exercise centers on the choice of the conditional distribution $f(\mathbf{x}|\mathbf{z})$. This has to be considered in the context of individual problems but there is one further simplification which applies to all models. This simplification involves making explicit what is already implicit in our formulation. The fact that the $\mathbf{x}$'s are supposed to be indicators of $\mathbf{z}$ implies that the $\mathbf{x}$'s will be mutually correlated – because of their common dependence on some, at least, of the $\mathbf{z}$'s. Hence, if $\mathbf{z}$ were to be fixed, the source of those correlations would vanish. Conditional on $\mathbf{z}$, the $\mathbf{x}$'s would then be independent. If this were not so, it could be inferred that there was at least one other $\mathbf{z}$, not already included, giving rise to the correlations remaining. Sufficient $\mathbf{z}$'s therefore have to be included in the model to eliminate the correlations after conditioning of $\mathbf{z}$. It then follows that

$$f(x|z) = \prod_{i=1}^{n} f_i(x_i|z) \qquad [4]$$

This is often referred to as the assumption of conditional (or local) independence but it is not an assumption in the usual

sense. It is, rather, a statement of what is meant by saying that $\mathbf{z}$ explains the interdependence of the $\mathbf{x}$'s. It is, essentially, a definition of q as the smallest integer for which an equation of the form [4] can be constructed.

How this may be done in particular cases will be shown in the following sections, but there is an important general principle which offers a fruitful way forward. Distributions of the exponential family are widely used in statistical modeling because they lead to estimates with highly desirable properties such as sufficiency. They provide a rationale for many of the most important models used in statistics, such as generalized linear models.

Essentially the same properties can be utilized here. They are set out in the article entitled *The General Linear Latent Variable Model* in Bartholomew et al. (2011). The essential idea is to make what is sometimes called the 'natural' or 'canonical' parameter of the one-parameter exponential family distribution, a linear function of the latent variables. If that is done, it turns out that the posterior distribution of $\mathbf{z}$ given $\mathbf{x}$ of eqn [3] depends on the $\mathbf{x}$'s only through q linear combinations of the $\mathbf{x}$'s, which we may write

$$X_j = \sum_{i=1}^{p} \alpha_{ij} x_i \quad (j = 1, 2, \ldots, q) \qquad [5]$$

This is a remarkable result, which justifies the common practice of 'estimating' latent variables from sums, or linear combinations of observed variables.

Structure of the Family

As we have already noted, latent variables can be classified into several types. Many, like intelligence, are conceived of as being continuous, in which case we are looking for a scale on which individuals can be located. In other contexts, it is more appropriate to think of the latent variable as categorical. In that case individuals are supposed to belong to one of several classes, which may or may not be ordered. What is true of the latent variables is, of course, true for the manifest variables and the only essential difference between the various methods is in the types of variables for which they are appropriate. A convenient way of displaying the relationship between the methods is to introduce the fourfold classification of **Table 1**. We classify the manifest and the latent variables as 'metrical' or 'categorical.' In the former case we mean that they take values on some continuous or discrete scale of measurement; in the latter they fall into categories.

This classification is not exhaustive. It does not, for example, include cases where the two kinds of variables occur among the manifest (or latent) variables. Neither does it distinguish between continuous and discrete metrical variables nor between ordered and unordered categorical variables. Nevertheless, it does serve to provide a broad convenient framework in which to place the most widely used methods covered in this article. The terminology of the subject reflects the diverse origins of the subject accumulated over almost a century.

Table 1 Classification of latent variable methods

	Manifest variables	
	Metrical	*Categorical*
Latent variables		
Metrical	Factor analysis	Latent trait analysis
Categorical	Latent profile analysis	Latent class analysis

Members of the Family

Factor Analysis

This is the oldest and most widely used latent variable method. The model is usually written as

$$\mathbf{x} = \mu + \Lambda \mathbf{z} + \mathbf{e} \qquad [6]$$

where $E(\mathbf{z}) = E(\mathbf{e}) = 0$; $\mathrm{cov}(\mathbf{e}) = \Psi$, a diagonal matrix; $\mathrm{cov}(\mathbf{z},\mathbf{e}) = 0$; and $\mathbf{z} \sim N(0, 1)$. An equivalent way of writing the model, which conforms more closely to the general treatment above, is to specify the conditional distribution of $\mathbf{x}$ given $\mathbf{z}$ as

$$\mathbf{x}|\mathbf{z} \sim N(\mu + \Lambda \mathbf{z}, \psi) \qquad [7]$$

which makes it clear that $\mathbf{z}$ influences $\mathbf{x}$ only through its mean, which is linear in $\mathbf{z}$. The marginal distribution of $\mathbf{x}$ is $N(\mu, \Lambda\Lambda' + \Psi)$ and it is from this that the parameters Λ and Ψ must be estimated. The matrix $\Lambda\Lambda' + \Psi$ is sometimes referred to as the covariance structure.

Fitting the model consists in determining Λ and Ψ, which make the fitted and observed covariances of the $\mathbf{x}$'s as close as possible. This can be done without invoking the distributional assumptions at all since the covariance structure derived from eqn [6] is the same, regardless of the assumptions about the form of the distributions of $\mathbf{z}$ and $\mathbf{e}$. However, without such assumptions nothing can be said about goodness of fit or the sampling variation of the estimators.

Posterior analysis allows the distribution of $\mathbf{z}$ given $\mathbf{x}$ to be determined, which for the factor model leads to

$$\mathbf{z}|\mathbf{x} \sim N\left(\Lambda \sum^{-1} \mathbf{x} - \mu\right), \left(I + \Lambda' \psi^{-1} \Lambda\right) \qquad [8]$$

where $\sum = \Lambda\Lambda' + \Psi$. As predictors of $\mathbf{z}$ given $\mathbf{x}$, we can use the mean values of this distribution, replacing the parameters by their sample estimates.

Interpretation and Rotation in the Case of the Factor Model

The interpretation of factors involves procedures that are common to all linear latent variable models. They are most familiar in the context of factor analysis so, although treated here, their generality must be emphasized. The problem may arise in two forms. If there is some idea of what factors to expect (as in the arithmetical ability example above), the question is how to confirm their existence. If, on the other hand, the analysis is purely exploratory, further guidance is needed on how to assign meaning to any factor that is found. The essential idea for doing this is to look at the relationships between the latent and manifest variables. This is facilitated by noting that the element λ_{ij} of Λ may be interpreted as the correlation between $\mathbf{x}_i$ and $\mathbf{z}_j$.

Manifest variables, which are highly correlated with $\mathbf{z}_i$ say, have a lot in common with $\mathbf{z}_i$ which, in turn, is highly

influential in determining those **x**'s. It must then be asked what it is that those **x**'s have in common with one another which they also share with $\mathbf{z}_i$. Interpretation is often facilitated by a process known as 'rotation.' Thus far the treatment has supposed that there was only one solution to the problem of fitting the model. In fact there are infinitely many models, which all predict the same covariance structure. These solutions can be generated from one another by a procedure known as 'rotation' (because of its geometrical interpretation). Each such solution represents an equivalent way of describing the latent space, but some ways may be easier to interpret than others. For example, a solution for Λ which has, at most, one nonzero value in each row implies that the **x**'s have been divided into disjoint groups, each group depending on a single latent variable. That latent variable is then interpreted in the light of what the members of that subset have in common.

Latent Class Models

If the latent space consists of a finite (usually small) set of classes and if the manifest variables are also categorical, the bottom right cell of Table 1 applies. The commonest case is where the manifest variables are binary. If there are c latent classes, the prior distribution $f(\mathbf{z})$ becomes a discrete probability distribution over the classes, η_j being the probability of belonging to class j. In this case these probabilities can be treated as unknown parameters to be estimated. For convenience, the two values which each $\mathbf{x}_i$ takes are coded as 1 and 0, the conditional distributions $f_i(\mathbf{x}_i|\mathbf{z})$ consists of two probabilities: $\Pr\{\mathbf{x}_i = 1|\mathbf{z}\}$ and $\Pr\{\mathbf{x}_i = 0|\mathbf{z}\}$. The obvious choice for the distribution of $\mathbf{x}_i$ is the Bernoulli distribution written as

$$f_i(x_i|j) = \{\pi_i(j)\}^{x_i}\{1-\pi_i(j)\}^{1-x_i} \quad x_i = 0,1 \quad j = 1,2,\ldots,c \qquad [9]$$

The joint probability distribution of **x** is then

$$f(x) = \sum_{j=1}^{c}\eta_j\prod_{i=1}^{p}\{\pi_i(j)\}^{x_i}\{1-\pi_i(j)\}^{1-x_i} \qquad [10]$$

This can be used to construct the likelihood function from which the parameters may be estimated.

Posterior analysis for this case is concerned with allocating individuals to latent classes after **x** has been observed and this is done easily by substituting into eqn [3]. This gives us the probability that an individual with observed vector **x** belongs to each of the classes. The number of parameters in this model increases rapidly with c and serious problems of identifiability arise if there are more than, say, four or five classes. Also the standard errors of the parameters estimates also increase rapidly as c increases.

Latent Trait Models

These models were devised, primarily, mainly for use in educational testing where the latent trait refers to some ability. Thus there is usually only one latent variable, representing that ability, and many indicators. The latter are often binary, corresponding to responses to the items being 'right' or 'wrong.' Latent trait modeling has become a specialized field, often referred to as item response theory with a literature and notation of its own. The model may also be used in other fields, such as sociology, where it may be more appropriate to introduce several latent variables.

A latent trait model with binary **x**'s is similar to a latent class model. The prior distribution is now continuous and will usually be taken as standard normal. The response variables will be Bernoulli random variables but now they depend on the continuous latent variables. Since the Bernoulli distribution is a member of the exponential family the appropriate form for $\pi_i(\mathbf{z})$ turns out to be

$$\text{logit}\ \pi_i(\mathbf{z}) = \alpha_i + \alpha_{i1}\mathbf{z}_1 + \alpha_{i2}\mathbf{z}_2 + \cdots + \alpha_{iq}\mathbf{z}_q \qquad [11]$$

Other versions of the model that exist are widely used in which the logit function on the left-hand side of eqn [11] is replaced by $\phi^{-1}(.)$, (the inverse standard normal distribution function). These give very similar results to eqn [11] but they lack the sufficiency properties. If $j = 1$ and if the α_{ij}s are the same for all i, the model is a random effects version of the Rasch model (see, for example, Bartholomew, 1996). In the latter model the trait values are taken as parameters rather than random variables so, in the strict sense of classical inference, the Rasch model is not a latent variable model.

Other Models

The latent profile models of Table 1 have not been included here because they have found relatively little practical application. However, it has also been shown by Molenaar and von Eye (1994) that they are virtually indistinguishable from factor models in the sense that they have an equivalent covariance structure. Nor have we considered hybrid models in which manifest and latent variables may be mixed type – discrete or continuous. A particular advantage of our general approach is that it lends itself to the treatment of all such models as exemplified, for example, in Bartholomew et al. (2011).

Relationships between Latent Variables

In much sociological research, the interest is not so much in the latent variables themselves as individual entities, but in the relationships between them. The interrelationship of manifest variables is a major subject of investigation in social science covering techniques such as path analysis, regression, log-linear analysis, and graphical models. It is natural to want to extend these models to include latent variables. This has given rise to linear structural relations modeling, which can be implemented using widely available software packages such as LISREL, Mplus, AMOS, and EQS.

In essence, such models have two parts: (1) a measurement model which supposes that each latent variable is linked to its own set of indicators through a factor model and (2) a structural model which specifies the (linear) relationships among the latent variables. Such a model is fitted by equating the observed and theoretical covariance matrices. A much more general framework, which allows a wider range of models, is provided by Bartholomew et al. (2011). Although these methods are very widely used, serious questions have been raised about the identifiability of the models (see Anderson

and Gerbing, 1988; Croon and Bolck, 1997; Bartholomew et al., 2011). These authors have suggested that it may be better to separate the measurement and structural parts of the analysis. This can be done by constructing 'estimates' of the latent variables and then exploring their interrelationships by the traditional methods used for manifest variables.

Estimation of Parameters

The feature of latent variable models which has posed considerable practical problems in the past has been the large number of unknown parameters that have to be estimated. For example, a standard factor analysis model with p variables and q factors involves $pq + q$ parameters and since p may easily exceed 10 or, even 100 this leads, inevitably, to large numbers of parameters. In the early days of factor analysis, great ingenuity had to be exercised to devise methods of estimating the parameters which were computationally feasible. The calculation of standard errors was almost impossible and this led, perhaps, to overoptimistic claims about what had been established. Modern computing facilities have radically altered the situation but words of caution are still in order.

General methods such as maximum likelihood are, of course, available and they have the great advantage of yielding asymptotic standard errors and covariances of the estimators. Bayesian methods are, likewise, not restricted, in principle at least, by the number of parameters. The latter provide estimates of the posterior distributions of the parameters, which provide a more complete picture of the uncertainty surrounding the estimates. Indeed, in a certain sense, the two approaches may be said to have converged when there is a large number of parameters to be estimated; the justification for this remark will become clearer as we proceed.

The standard asymptotic theory of maximum likelihood estimation depends on the behavior of the likelihood in the immediate neighborhood of the maximum. Empirical work with the method has shown that the sampling distribution only approaches the normal form implied by the asymptotic theory, if the sample size is very large indeed. This means that the asymptotic standard errors may not be an adequate approximation in many practical situations. Furthermore, the approach to the maximum of the standard iterative methods may be extremely slow. With problems involving relatively small number of parameters and with adequate computing power, this is not usually a serious problem and the software, which most practical applications use has been based, has often been equal to the task. Nevertheless, there are considerable attractions in moving to Bayesian methods, especially as the number of parameters increases.

Bayesian methods involve approximating the posterior distribution of the parameters. This enables one to find the maximum of this distribution and, if required, other properties of the posterior distribution. Provided that the prior distribution chosen for the parameters is fairly 'flat' there will be very little difference between the posterior distribution and the likelihood function in the neighborhood of the maximum. Hence the method is thus, for all practical purposes, an approximation to the method of maximum likelihood.

The method, known as Markov Chain Monte Carlo, generates the empirical posterior distribution from which summary values, like the maximum, can be estimated. The Markov Chain part of the name comes from the fact that the posterior distribution emerges as the steady state of a certain Markov chain. Repeated empirical realizations of the chain then generate a random sample from the posterior distribution. The method, illustrated numerically, is described in Bartholomew et al. (2011).

The particular attractiveness of the method is that it involves a very large number of very simple steps – a task for which computers are ideally suited. It therefore offers a way forward in what have, hitherto, been extremely intractable numerical problems.

Historical Background

Factor analysis was invented by Spearman (1904) for the specific purpose of operationalizing the notion of general intelligence. He remained wedded to the view that there was a single dominant latent variable of human ability which he named 'g' which accounted for most of the variation in observed performance. This idea was challenged by Godfrey Thomson who introduced what he first called the 'sampling of bonds' model which had an identical correlation structure (see, for example, Thomson, 1938). Over the years, Thomson was at pains to emphasize that his model had been produced primarily to show that there were more than one model which would account equally well for the data rather than that it corresponded to reality. More recently, what has become known as Thomson's 'bonds model,' has received more attention (see, for example, Bartholomew et al., 2009) as a serious competitor for Spearman's model in that there is no good biological ground for distinguishing between them. It can also be generalized in various ways which have considerable practical plausibility.

Following Spearman, Thurstone (1947) emphasized the multifactorial approach and, for that purpose, generalized Spearman's treatment to allow for several factors. At that time, factor analysis was ahead of its time in two senses. First, it was a sophisticated multivariate technique introduced long before the statistical technology was available. In consequence, its development was somewhat idiosyncratic and its separation from the statistical mainstream gave it an alien appearance, which persists to this day and still causes some suspicion and misunderstanding. Second, it is a computer-intensive technique whose full potential could only be realized with the arrival of the powerful electronic computers in the 1980s. This lack distorted the early development of the subject by the need to concentrate on the search for computational simplifications.

Latent structure analysis, which covers the remaining cells of **Table 1**, was introduced by Lazarsfeld after the World War II, with a view to its applications in sociology. A book-length treatment, by Lazarsfeld and Henry (1968), has held the field for many years as the definitive source of information but this has now been superseded by a new generation of books of which Heinen (1996) is both comprehensive and relatively recent.

Latent structure analysis came on the scene half a century after factor analysis, and in a different disciplinary context. For that reason there was, until very recently, little cross-fertilization between the two fields. When viewed from a level of sufficient generality, the methods are essentially the same.

In the postwar era, more powerful methods became available but the whole field has largely remained a set of distinct subspecialisms each with its own literature and technology. It is over 40 years since Anderson (1959) pointed out that all latent methods shared a common conceptual framework but his insight has been slow to yield its full potential. The classification of methods as given in **Table 1** was made on the basis of a common approach in Bartholomew (1984), the culmination of which is to be seen in Bartholomew et al. (2011).

Future Developments

The advent of massive computer power has changed the practice of multivariate analysis radically, and of latent variable analysis in particular. It is not possible to foresee all of the consequences of this development. The limiting factor is no longer computing power but of getting data of sufficient quality and quantity to justify the very complicated models which the theory provides and computers can handle. The precision with which models with many parameters can be estimated may often be very low unless the sample size runs into many thousands. This makes it all the more important to estimate the sampling variability adequately of the estimates of the parameters on which the interpretation depends. Traditionally this has been done by finding asymptotic standard errors but these can be very imprecise, as we have already remarked. However, it is now possible to supplement these results by resampling methods such as the bootstrap or other straightforward simulation methods.

There are other fields in which latent variable models are, or may be, used which currently exist in isolation. Some of these are covered in Bartholomew (2013). One generalization, which may not be obvious, is the latent time series. Some work has been done for the case where the latent process is a Markov chain. In this area the term 'hidden' is often used instead of 'latent' and this helps to conceal the family connections (for an introduction see Zucchini and MacDonald, 2009). An application in a more traditional time series context will be found in Harvey and Chung (2000). Also, there has been a great deal of important work done by economists on what they call unobserved heterogeneity. This essentially involves the introduction of latent variables into econometric models and there is substantial scope for new work in this area.

Notes on Bibliography

The literature in this field is enormous. On the one hand, there are classics dating back to the early years of the last century or, in the case of latent structure models, almost as long. These are distinguished from current work by three things. First they were written before the computer era and much attention is typically given to the complications of computation. Second, they were written, largely, from within particular disciplinary perspectives and hence suffer from lack of recognition of the wider context. Third, being mainly the work of those whose interests lay in substantive fields, they are strong on substantive relevance but sometimes weak in technical generality. Some examples are provided in the following Bibliography but they should only be read in the light of these limitations.

A useful source on factor analysis is Cudeck and McCullum (2007). This publication marked the 100th anniversary of Spearman's introduction of the method and it looks backward and forward. A very wide-ranging treatment, covering latent structure methods more generally, is provided by Skrondal and Rabe-Hesketh (2004). A useful text on the theoretical basis of latent variable methods is provided by Bartholomew et al. (2011). At the textbook level, for students in the social and behavioral sciences, there is a good deal relating to latent variable analysis in Bartholomew et al. (2008). The references in these books will lead on to much reliable information for those new to the field.

Abstract

Educational assessments, psychological scales, and social surveys often generate data in the form of a two-way array of discrete response data for N subjects (examinees, respondents, etc.) and J probes (test, scale, or survey items). Subjects' responses to the probes may be viewed as fallible measures of one or more underlying constructs, represented generically by a scalar or vector-valued index {latent variable} for each subject. When the response variables are discrete-valued, item response theory (IRT) and its variants provide a set of modeling and estimation tools for making inferences about the relationships between the X_{ij} and the latent variable(s) θ_i and about subjects' location in the latent structure represented by θ. This article reviews standard parametric IRT models and estimation methods, extensions to compelx data analysis setting by way of a hierarchical Bayes formulation, nonparametric approaches to IRT, and selected applications in education, psychology, the social sciences, and biostatistics. Extensions of IRT to handle cognitively diagnostic assessment are briefly sketched, and similarities between IRT and Bayesian inference networks are pointed out.

In education and the social sciences, we often ask subjects to respond to a set of items (questions, statements, or tasks) on survey forms, self-report inventories, and mental tests, that are coded as discrete – often dichotomous – variables. In many settings it is natural to think, in analogy with factor analysis (*see* Factor Analysis and Latent Structure Analysis: Confirmatory Factor Analysis; Factor Analysis and Latent Variable Models in Personality Psychology), that there is one or more continuous latent variables for each subject – such as political agency, extrovertedness, or ability in some area of mathematics – that can be measured or estimated using the positive and negative responses to these items. Item Response Theory (IRT), and specializations such as the Rasch Model, refer to a set of statistical modeling and estimation tools for making inferences about one or more continuous latent variables from this kind of multivariate discrete data.

Introduction: the Rasch Model

As an example, consider a test of transitive reasoning in school children (e.g., Sijtsma and Verweij, 1999). An item may consist of three rods, A, B, and C, of differing lengths. The child is given evidence that Length(A) < Length(B), and Length(B) < Length(C), and is asked to deduce a relationship between Length(A) and Length(C); his or her answer is scored 1 if it is correct and 0 if it is incorrect. Let us say that J such items, involving different types of objects and attributes (balls of varying weight, disks of varying area, etc.) and different numbers of objects, make up a test given to N school children. If the scored responses were continuous we might build a two-way additive ANOVA model in which child i's response to item j, X_{ij}, is the sum (or difference) of the child's achieved transitive reasoning level, and the item's innate difficulty, as determined by the attribute on which objects are compared and the number of objects being compared.

However, since the responses are dichotomous $X_{ij} = 0$ or 1, we need a model specifying the *probability* that $X_{ij} = 1$, in terms of the child's transitive reasoning ability and the item's difficulty. One of the earliest such models, developed by the Danish mathematician Georg Rasch (Rasch 1960), specifies

$$P_j(\theta_i) \equiv P\left[X_{ij} = 1 \middle| \theta_i, \beta_j\right] = \frac{\exp(\theta_i - \beta_j)}{1 + \exp(\theta_i - \beta_j)}, \quad i = 1, \ldots, N, j = 1, \ldots, J \qquad [1]$$

where θ_i represents child i's transitive reasoning level, and β_j represents the *difficulty* of the item: as the latent variable θ_i increases, the probability of getting the item right increases, and as the difficulty parameter β_j increases, the probability of getting the item right decreases. The Rasch model, together with similar models using different forms for $P_j(\theta_i)$ developed by Jane Loevinger (Loevinger, 1948) and Frederic M Lord (Lord, 1952), became the core of what is now item response theory.

On the logit scale, the Rasch model has exactly the two-way additive ANOVA structure we sought:

$$\text{logit } P_j(\theta_i) = \ln \frac{P_j(\theta)}{1 - P_j(\theta_i)} = \theta_i - \beta_j.$$

We further assume local independence among item responses, i.e., all X_{ij} are conditionally independent, given θs and βs. Letting x_{ij} denote the observed values of X_{ij}, we may write the likelihood for the Rasch model as

$$\begin{aligned} P\left[X_{ij} = x_{ij}, i = 1, \ldots, N, j = 1, \ldots, J \middle| \theta_1, \ldots, \theta_N; \beta_1, \ldots, \beta_J\right] \\ = \prod_{i=1}^{N} \prod_{j=1}^{J} P_j(\theta_i)^{x_{ij}} \left[1 - P_j(\theta_i)\right]^{1 - x_{ij}}. \end{aligned} \qquad [2]$$

An up-to date account of the Rasch model and its various extensions is given by Fischer and Molenaar (1995), to whom we also refer for historical notes and references.

The Rasch model in Eqn. [1] has the interesting invariance property that the odds ratio comparing two items j and k is

$$\frac{P_j(\theta_i)}{1-P_j(\theta_i)}\cdot\frac{1-P_k(\theta_i)}{P_k(\theta_i)} = \exp\beta_k - \beta_j$$

independent of θ_i. Hence in our example, the 'difficulty' of two items involving different transitive reasoning settings can be compared, in principle, using any convenient sample of subjects regardless of their transitive reasoning level (in practice, subjects still contribute at least 'small sample bias' to the estimated βs). Similarly, the odds ratio comparing two subjects is independent of the item difficulty parameters. These two invariance properties are instances of 'specific objectivity,' a property Rasch considered important in defining a measurement model and from which Eqn. [1] can be derived (see Fischer and Molenaar, 1995). The Rasch model is also closely related to the Bradley–Terry model of paired comparisons. Consider two items j and k for which $\beta_j < \beta_k$. For any subject i who got only one item right, it follows from Eqn. [1] that the probability that the easier item was correct is

$$P\left[X_{ij} = 1 \middle| X_{ij} + X_{ik} = 1, \theta_i, \beta_j, \beta_k\right] = \frac{\exp(\beta_k - \beta_j)}{1+\exp(\beta_k - \beta_j)} \quad [3]$$

independent of θ_i; this is exactly the Bradley–Terry model with parameters $\phi_j = -\beta_j$. The lack of dependence on θ_i on the right can also be used to construct empirical tests of the Rasch model, since the probability in Eqn. [3] can be estimated without assuming the Rasch model and should be the same in any subpopulation of subjects in which the Rasch model applies.

Estimation in the Rasch Model

Two estimation methods are traditionally associated with the Rasch model, joint maximum likelihood (JML) and conditional maximum likelihood (CML). One can maximize Eqn. [2] jointly in the θs and βs, by numerically solving the 'normal equations' obtained by setting all partial derivatives of the logarithm of Eqn. [2] equal to zero; the maximizing values $\widehat{\theta}_i$ and $\widehat{\beta}_j$ are called joint maximum likelihood estimators (JMLEs). However, the JMLEs turn out to be *inconsistent*, or asymptotically biased: suppose we are primarily interested in estimating β_js; it need not be the case that each $\widehat{\beta}_j$ converges to β_j as we increase the subject sample size N, keeping the number of items J fixed. Indeed, as N increases, more θ_is are also added to the model: intuitively, some information must be expended on estimating them, and there is not enough information left over to improve the estimates of the β_is. One solution to this problem is to exploit the fact that in the Rasch model, a sufficient statistic for each θ_i is subject i's total number correct score, $X_{i+} = \sum_{j=1}^{J} X_{ij}$. If the likelihood in Eqn. [2] is divided by the joint likelihood for the observed x_{i+}s, the resulting conditional likelihood contains only the β_j parameters, and the conditional maximum likelihood estimators (CMLEs) $\widehat{\beta}_j$ obtained by maximizing this new likelihood are consistent (asymptotically unbiased) as N grows and J stays fixed. For this reason, CML estimates are usually preferred over JML estimates. Additional details are provided by Andersen (1980), whose earlier work demonstrated the inconsistency problem with JML, and established consistency of CML for the Rasch model.

Another approach to solving the inconsistency problem with JML is to assume the θ_i are independent random effects following a common (discrete or continuous) distribution $f(\theta|\lambda)$. Integrating over θ_i for each subject yields the marginal likelihood

$$\prod_{i=1}^{N}\int\prod_{j=1}^{J} P_j(\theta_i)^{x_{ij}}\left[1-P_j(\theta_i)\right]^{1-x_{ij}} f(\theta_i|\lambda)\mathrm{d}\theta_i \quad [4]$$

and maximizing this with respect to β_is and λ (using an E-M algorithm, for example) yields what are called maximum marginal likelihood (MML) estimates $\widehat{\beta}_j$ and $\widehat{\lambda}$. These MML estimates are also consistent (asymptotically unbiased). The method based on Eqn. [4] can be interpreted as an empirical Bayes method; it also links the Rasch model directly with other latent variable approaches such as factor analysis, where the latent variable θ_i is treated as an unobserved random variable, or equivalently as completely missing data (*see* Factor Analysis and Latent Variable Models in Personality Psychology).

Finally, it can be shown that under Eqn. [4], the marginal distribution of the data follows a log-linear model for the 2^J table of the form

$$\ln p(x_{i1},\ldots,x_{iJ}) = \alpha - \sum_{j=1}^{J}\beta_j x_{ij} + \sum_{k=0}^{J}\gamma_k \chi(x_{i+} = k)$$

where $x(S) = 1$ if statement S is true, and 0 otherwise. This is the log-linear model of quasisymmetry; the connection between the Rasch model and the quasi-symmetry model has been independently discovered innumerable times in the literature. Lindsay et al. (1991) give a reasonably complete account of the connection with quasisymmetry and consequences for the identifiability of the distribution $f(\theta \mid \lambda)$ in a semiparametric formulation of Eqn. [4].

Parametric IRT

Other parametric IRT models have been developed for situations in which the Rasch model does not fit, while retaining the ideas of dichotomous ($X_{ij} \in \{0, 1\}$) or at least polytomous ($X_{ij} \in \{0, 1, \ldots, K-1\}$) item scores, a unidimensional (or low-dimensional) latent variable θ_i characterizing subjects, a low-dimensional parameter β_j characterizing items, and local (conditional) independence of all item responses X_{ij} given all parameters. An accessible review of developments in parametric IRT in the 1960s, 1970s and 1980s is given by Hambleton et al. (1991).

A simple generalization of the Rasch model that is often useful for dichotomously-scored items,

$$P_j(\theta_i) = \frac{\exp\left[\alpha_j(\theta_i - \beta_j)\right]}{1+\exp\left[\alpha_j(\theta_i - \beta_j)\right]} \quad [5]$$

is called the two-parameter logistic (2PL) model. In the 2PL model, the slope parameters $\langle_{jk}$ are called 'discrimination parameters,' and they control the Fisher information for estimating the θs. Again, the location parameters β_j play the role of

'difficulty parameters'; they also determine the value of θ maximizing the Fisher information. The three-parameter logistic (3PL) model adds a nonzero lower asymptote to Eqn. [3], to model random or exchangeable response behavior by low-θ subjects. Further generalizations, discussed in the next several paragraphs, are treated at length by Fischer and Molenaar (1995) and van der Linden and Hambleton (1997).

Additional covariates and other structures can be incorporated into these models as regression terms. For example, in the linear logistic test model (LLTM), the difficulty parameters β_j in the Rasch model are rewritten as linear combinations of K basic parameters $/_k$ with weights q_{jk}, and

$$\text{logit } P_j(\theta_i) = \theta_i - \sum_{k=1}^{k} q_{jk}\eta_k.$$

The matrix $Q = [q_{jk}]$ is usually obtained as a regression model matrix from *a priori* analysis of the items; for example, in the transitive reasoning example described in Sect. 1, the q_{jk} might indicate what kind and how many objects were used for each item. By contrast, multidimensional compensatory IRT models decompose the unidimensional θ_i parameter into an item-dependent linear combination of underlying traits, e.g.,

$$\text{logit } P_j(\theta_i) = \sum_{d=1}^{D} \alpha_{jd}\theta_{id} - \beta_j.$$

For example, mathematics word problems may involve both a math component, θ_{i1}, and a verbal component θ_{i2} in different proportions in different problems, as determined by the discrimination parameters $\langle_{jd}$. In some settings, the $\langle_{jd}$ may be fixed *a priori*, like the q_{jk} in the LLTM model, and in other settings they may be estimated analogously to factor loadings in Factor Analysis. Multiplicative or conjunctive IRT models combine unidimensional models for components of response in a product $P_j(\theta_i) = \Pi_d^D = 1\, P_{jd}(\theta_{id})$ where $P_{jd}(\theta_{id})$ are parametric unidimensional dichotomous response functions. The usual interpretation is that the $P_{jd}(\theta_{id})$ are probabilities of correctly performing component skills or subtasks, which must be done in conjunction in order to generate a correct response to the item itself; this model is sometimes referred to as the multicomponent latent trait model (MLTM).

Probit versions of all the above models, in which the logit function is replaced with $\Phi^{-1}(p)$, the inverse standard normal distribution function, are also in use. Aside from a trivial rescaling of the parameters, there is little difference in practice between the probit and logit models; the choice depends mostly on computational expedience.

IRT model can also be extended to handle polytomous or multicategory items, $X_{ij} \in \{0, 1, 2, \ldots, K-1\}$, in much the same way that logistic regression models are extended polytomous data: in the 'graded response model' (GRM) the cumulative logit, logit $P[X_{ij} > c|\theta_i, \beta_j]$, is linear in θ_i; in the 'sequential model' (SM) the continuation-ratio logit, logit $P[X_{ij} > c|X_{ij} > c-1, \theta_i, \beta_j]$, is linear in θ_i; and in the 'partial credit model' (PCM) the adjacent-category logit, logit $P[X_{ij} = c+1|X_{ij} \in \{c, c+1\}, \theta_i, \beta_j]$, is linear in θ_i. Again, probit reformulations of these models are straightforward. When the discrimination parameters are all non-negative, the cumulative response curves in any of these models is nondecreasing (Hemker et al. 1997), a condition referred to as 'monotonicity.' By contrast, IRT formulations of direct-response probabilistic unfolding models, also known as proximity models or parallelogram models, have unimodal response curves that peak near the location β_j of the item.

As was the case for the Rasch model discussed in Sect. 2, JML estimates for IRT models are relatively easy to set up but generally inconsistent (asymptotically biased); CML methods can be used when simple sufficient statistics are available. MML methods based on applying an E-M algorithm to Eqn. [4], with $P_j(\theta_i)$ redefined according to one of the above parametric forms, are most common, however. The recent development of Markov Chain Monte Carlo (MCMC) integration methods for Bayesian statistics (*see* Markov Chain Monte Carlo Methods) provides an alternative to these methods. Patz and Junker (1999) sketch a general MCMC methodology for parametric IRT models, and Johnson and Albert (1999) survey a range of related applications from a working Bayesian statistician's perspective.

The IRT toolbox has been pushed forward in recent years by the needs of both large-scale educational assessment surveys (e.g., Johnson et al. 1994) and cognitively based assessment models (e.g., Nichols et al. 1995). To accommodate finer structure in the latent space, as well as to incorporate subject and item covariates in the model, it is useful to reformulate the IRT framework as a two-way hierarchical Bayes structure for N individuals and J response variables, as in **Figure 1**. In addition to the item response functions $P_j(\theta_i) = P(\theta_i; \beta_j)$ in **Figure 1**, f_i and g_j are prior distributions on the latent variables θ and item parameters β respectively (both of which may be multidimensional), and $\lfloor_f$ and $\lfloor_g$ represent sets of hyperparameters needed to specify these prior distributions.

$$\text{First level:} \quad X_{ij} \sim P(\theta_i; \beta_j)^{X_{ij}}\,[1 - P(\theta_i; \beta_j)]^{(1-X_{ij})},$$

$$i = 1,\ldots, N;\ j = 1,\ldots, J$$

$$\text{Second level:} \quad \theta_i \sim f_i(\theta|\lambda_f), \quad \text{each } i$$

$$\beta_j \sim g_j(\beta|\lambda_g), \quad \text{each } j$$

$$\text{Third level:} \quad \lambda_f \sim \phi_f(\lambda_f)$$

$$\lambda_g \sim \phi_g(\lambda_g)$$

Figure 1 Two-way hierarchical structure for N individuals and J dichotomous response variables. Factors in the first level are independent and are multiplied together to form a likelihood for the response data matrix $[X_{ij}]$. Factors in the second and third levels are also independent, and covariates and special structure for the latent variables and item parameters may be introduced in these levels.

The model in **Figure 1** is expressed for dichotomous items but can be generalized easily to polytomous items or combinations of item types, incomplete data, and so forth (e.g., Patz and Junker 1999). The MML formulation discussed in the previous paragraph is obtained by taking $f_i(\theta)$ to be a single population distribution not dependent on j for the latent trait, and taking g_j to be flat priors not depending on j for the item parameters.

Nonparametric IRT

Nonparametric IRT refers to several related methodologies for working with item response data without fully committing to any particular well-known family of parametric item response theory models. Some topics in nonparametric IRT are considered in van der Linden and Hambleton (1997) and Boomsma et al. (2001), and several current issues are surveyed in a special issue of *Applied Psychological Measurement* (Junker and Sijtsma, 2001).

Modern nonparametric scaling methods include the 'essential independence' (EI) approach of Stout and his students and colleagues (e.g., Stout et al., 1996), and the Mokken scaling approach (e.g., Hemker et al., 1995); both methods are related to Cronbach's alpha bound on reliability. Mokken scaling is very good at finding groups of items that are highly discriminating among subjects; Stout's methods tend to identify groups of items that narrowly satisfy LI/EI, M, and U better. Ramsay (e.g., Ramsay, 1996) has developed computational tools for estimating item response functions nonparametrically, and for visualizing the dimensionality of θ in terms of the surface in the J-dimensional unit cube generated by the joint likelihood for $X_{i1}, \ldots, X_{iJ}$ as θ_i varies.

Some Applications

Parametric and nonparametric IRT methods are routinely used to assess the quality of individual items and sets of items in educational measurement work (Linn, 1989) and to elucidate experimental design and statistical estimation issues when performances of examinees who sit for different versions of the same exam must be compared; such work goes under the name test equating. A similar problem arises in the scoring of sequentially-designed, computerized adaptive tests (e.g., Sands et al., 1997). IRT modeling has also elucidated research into the assessment of sociological bias (differential item functioning) on standardized test items (Holland and Wainer, 1993) and the detection and diagnosis of subject outliers (Meijer, 1996). Related work includes the study of rater effects (e.g., Patz et al. 2000) and matrix-sampling and the incorporation of group effects and other item and subject covariates in educational assessment survey work (Johnson et al., 1994).

In the broader social sciences and related areas, IRT has also played a substantial role. The Rasch model has long been applied in social survey work; see, for example, Duncan (1985). The Rasch model and other IRT models can also be applied to model subject heterogeneity in estimating a closed population from multiple-recapture census data (*see* Censuses: History and Methods); Fienberg et al. (1999) recently surveyed this methodology and compared Bayesian IRT models with standard log-linear models in this context. Applications to multiple outcomes of designed experiments and to panel data are indicated in the volumes by Fischer and Molenaar (1995) and van der Linden and Hambleton (1997). Sijtsma and Verweij (1999) apply nonparametric IRT to scale construction in developmental psychology; and Nichols et al. (1995) collect many applications of IRT and related Bayesian inference network models (*see* Bayesian Graphical Models and Networks; Mislevy, 1996) in cognitive diagnosis. Applications of parametric and nonparametric IRT to psychiatric scales include Gibbons et al. (1985), Santor et al. (1995) and Kim and Pilkonis (1999). In biostatistics Legler and Ryan (1997) use IRT to model multiple physical outcomes in the study of birth defects.

Summary

Item response theory (IRT) has grown from its roots in postwar mental-testing problems, through intensive use in educational measurements in the 1970s, 1980s, and 1990s, to become a mature statistical toolkit for modeling of multivariate discrete response data using subject-level latent variables. Applications of IRT can be found throughout the social sciences and related areas, from education, psychology, economics, and demography to medical research.

Most parametric IRT models would be recognizable by modern statisticians as mixed-effects multivariate generalized linear models, but IRT has benefited from interaction with all parts of the statistical community. Almost any assessment phenomenon – from between-subject dependence due to institutional or sociological factors, to behavioral aspects of raters, to the analysis of item responses in terms of requisite subject or item features – can be expressed in the hierarchical mixture/Bayes modeling framework of **Figure 1**, because of its conceptual simplicity. Recent advances in computation, and MCMC methods in particular, have made it possible to estimate a vastly wider variety of these models than would have been imaginable even in the early 1990s however the more complicated models typically also make higher sample-size demands. Nonparametric IRT approaches also rely on computationally intensive methods, including spline and kernel smoothing and bootstrap techniques, to estimate and test probability inequalities, stochastic ordering properties, and similar features of the models. Questions motivating both parametric and nonparametric IRT modeling inevitably involve identifying the phenomena that are worth detailed modeling, and seeing if the computational and data collection machinery can be pushed to be informative about reasonable models of these phenomena.

Hambleton et al. (1991) provide a fairly straightforward introduction to IRT in educational testing; Andersen (1980) presents the Rasch model in the context of other statistical models for the social sciences; and Fischer and Molenaar (1995) and van der Linden and Hambleton (1997) provide modern technical accounts. A broad range of current research issues in IRT is collected in Boomsma et al. (2001).

Factor Analysis and Latent Variable Models in Personality Psychology

Ralf Schulze, Anna-Lena Hilger, and Philipp M Engelberg, Bergische Universität Wuppertal, Wuppertal, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

A generalized model for latent structures is introduced as a general framework for the factor model to give an overview about modeling options in personality research. It is briefly described and it is shown that the factor model is one of many instances of the generalized linear latent variable model. Factor analysis as one of the most important multivariate methods in personality research is then presented with an emphasis on central issues in exploratory factor analysis. The presentation also addresses the role of confirmatory factor analysis as a method in personality research.

Introduction

Among the most central research questions of personality research are the following: What are the fundamental personality constructs and what are their relationships or what is their structure? Since constructs are commonly considered as unobserved or even unobservable variables (Bollen, 2002), personality psychology, like many other subdisciplines of psychology, can mainly be characterized as the investigation of stable psychological attributes that are not directly observed in empirical research. Nevertheless, it is always assumed that the constructs of personality psychology somehow relate to observable behavior, and that these relationships are the basis to make inferences about the existence and relations between the constructs.

The major models that are used in personality psychology to formalize the relationship between unobserved variables and observed indicators are described in this article. Unobserved variables are interchangeably called latent variables or factors in what follows. The focus will be put on basic statistical models with latent variables instead of (1) more philosophical approaches to the question of what the nature of the latent variables actually may be (cf Bollen, 2002; Borsboom et al., 2003) and (2) the many qualitatively different latent structures, like hierarchical and higher order models, for example, that are prominent in personality psychology and ability research (see Schulze, 2005).

Examples of latent variables are personality traits (e.g., extraversion) or abilities (e.g., fluid intelligence) which relate to observable or so-called manifest variables. Typical examples for manifest variables are the responses to the self-report items of a personality test. A basic premise of factor analytic models and the latent variable models considered in this article is that the manifest variables are influenced by one (or more) latent variable(s). That is, the factors are considered to be the cause for the responses. In this sense, the latent variables determine the responses and thereby the value of the indicators. If many indicators are determined by the same factor, which is a common design feature of measurement instruments in personality psychology, then the latent variable is called a common cause or common factor. Given that such common factors exist, the indicators share common variance, the extent of which depends on the strength of the relationships of the indicators with the common factors. A crucial function of factor analytic models therefore is the explanation of the shared variance (i.e., covariances) between manifest variables by the introduction of latent variables.

There are many different factor models that can be distinguished with respect to several theoretical and statistical features. To understand the differences and to be able to make an appropriate choice for a certain measurement purpose, it is helpful to examine the most important features. Among these features are the number and the properties of both latent and manifest variables.

In the statistical latent variable models, both manifest and latent variables can be defined as random variables, and they can be either discrete (categorical) or continuous. A common well-known classification scheme of variables is the concept of level of measurement (e.g., nominal, ordinal, and metric). However, since statistical methods do technically not depend on the level of measurement but mainly on distributional assumptions (Gaito, 1980), the distinction of discrete and continuous random variables is adopted in this article for the classification of both manifest and latent variables.

The distributional assumptions of the variables depend on this classification. A typical example for a discrete manifest variable is an item from an ability measure that can only be answered correctly or incorrectly. If this is the case, then the manifest variable is discrete with two possible values 0 and 1 only (i.e., dichotomous) and it follows a Bernoulli distribution. Also typical for personality research are Likert-type items that are ordinarily treated as categorized continuous variables and assumed to be sampled from a normal distribution.

The classification of latent variables as categorical or continuous depends entirely on theoretical assumptions. Intelligence, for example, is commonly considered to be a continuous trait following a normal distribution. On the other hand, latent variables can be conceptualized as categorical, like in theories of personality types or as is common in the area of personality disorders. In such cases, the latent variables follow a distribution for discrete random variables.

In the following passages, a general framework for latent variable models that includes both categorical and continuous manifest and latent variables will first be described. Next, a particular instance, the factor analytic model, will be presented in more detail as it is the most relevant in terms of frequency of use in personality research, and also because of its historical importance for the field.

A General Framework for Latent Variables

Latent variable models have a rather long and partly fragmented tradition as statistical models for psychological assessment. As a consequence, many psychometric models have been proposed that include different numbers and types of manifest and latent variables. Despite the partial fragmentation, the equivalence has been proven for some models from very different traditions (Takane and de Leeuw, 1987; Kamata and Bauer, 2008). Modern approaches integrate characteristics of diverse models and provide a general framework for latent variable modeling (McDonald, 1999; Skrondal and Rabe-Hesketh, 2004; Bartholomew et al., 2011). Among the benefits of using a general framework is that researchers are more flexible and can make sure that their model fits the data characteristics, instead of adjusting the data to fit the model requirements. It also facilitates insights into the commonalities of seemingly or traditionally different models of measurement. Even if special instances of the general model have been more common in personality research so far, the current development in personality research indicates that a wide range of models will be applied in future (Morizot et al., 2007).

The general framework for latent variables can best be described as a generalized linear model for latent variables (Skrondal and Rabe-Hesketh, 2004). Broadly speaking, the generalized linear framework allows us to model linear relations of both categorical and continuous dependent (manifest) and independent (latent) variables, or more generally, of variables sampled from distributions of the exponential family (see, e.g., Gill, 2000). The exponential family is a group of distributions whose functions can be rewritten in an exponential form. Exemplary members of the exponential family that are familiar to most researchers are the normal and the binomial distribution. Generalized linear latent models provide a framework for measurement models where either categorical or continuous observed responses are predicted by either categorical or continuous latent variables.

The Generalized Model for Latent Variables

The generalized model for latent variables consists of three components which will be very briefly introduced in the following passages. The first component of the model is a matrix of dependent observed variables Y (e.g., responses to items) sampled from a probability function of the exponential family. These random variables can be characterized by their respective expected value. For a normally distributed item (e.g., a self-report item) the expected value would simply be the mean for all respondents in the population. For a Bernoulli-distributed item (e.g., a dichotomous item scored as either correct or incorrect), the expected value would be the probability of choosing the correct option.

The second element of the model is the linear component v that represents an interim dependent variable in the model that is predicted by the latent explanatory variables η using the corresponding weights Λ. The latent explanatory variable can be continuous or categorical.

The third component of the generalized model for latent variables is the link function. With the link function it is possible to link the expected value of the distribution of Y to the linear component v. If Y is assumed to be normally distributed, the link function is the identity link. With the identity link, the expected value of Y can directly be linked with the linear component, resulting in a standard regression model with a latent predictor. If the dependent variable Y is not normally distributed because it is categorical, for example, different link functions have to be used. The expected value of the Bernoulli-distributed dichotomous variable, the probability of success can be linked with the linear component either with a logit link or a probit link. In other words, the link function is the part of the model where the generalization takes places. The use of different link functions provides a means to model not only normally distributed dependent variables but any dependent variables sampled from a distribution of the exponential family.

For the purpose of illustration assume that l respondents answered q items of a personality questionnaire which are determined by k latent variables. The response scale is treated as continuous and the responses are assumed to follow a multivariate normal distribution. The same assumption applies to the latent variables. In this case, the linear component v can be written in matrix notation as

$$v = \Lambda\eta \qquad [1]$$

where η is a $k \times l$ vector of values of the latent variables for every respondent and Λ is a $q \times k$ matrix of weights for every item. Given the assumptions stated above, the linear component can directly be linked to the expected values of the observed variables as follows:

$$E(Y) = \mu = \Lambda\eta \qquad [2]$$

$$Y = \Lambda\eta + \Psi E \qquad [3]$$

Equation [2] is consistent with the generalized linear latent model presentation. In eqn [3] the values of the observed variables are modeled and, hence, the error term E weighted by Ψ is part of the equation.

In the dichotomous case, the observed variables follow a Bernoulli distribution. Nevertheless, an underlying latent variable may still be normally distributed but the above given link function would no longer be appropriate in this case. The logit link is one of two options to link the expected values of Y, the probability of success, to the linear component:

$$E(Y) = P(Y = 1) = \frac{\exp(\Lambda\eta)}{1 + \exp(\Lambda\eta)} \qquad [4]$$

Alternatively, the probit link can be used:

$$E(Y) = P(Y = 1) = \phi(\Lambda\eta) \qquad [5]$$

where ϕ is the standard normal cumulative distribution function. The two models in eqns [2] and [4] differ in type and distribution of the observed variables but the same distributional assumptions apply to the explanatory latent variables in both models.

In sum, the generalized linear model for latent variables provides a very flexible framework for measurement models in psychology. It encompasses many popular models for latent variables as special cases that have often been seen as distinct. For example, the model for dichotomous responses in eqns [4] or [5] is a two-parameter Item Response Theory (IRT) model or

a factor model for categorical (dichotomous) variables (see Christoffersson, 1975; Takane and de Leeuw, 1987; Kamata and Bauer, 2008). Yet another example for a popular special case is the first model in eqns [2] and [3] that is known as a factor model, which will be presented in more detail in the next section. It should also be noted that, in addition to IRT models and factor models, the framework includes latent class models, longitudinal models, multilevel models, and structural equation models (Skrondal and Rabe-Hesketh, 2004).

Factor Analysis

Factor analysis is more than 100 years old and has gradually evolved over time into a multifarious statistical technique that is part of the generalized linear latent variable model class (see Bartholomew, 2007). It is probably not an overestimation of its impact on personality research in particular that without its invention personality theory would not be the same as we know it. Hence, at least a basic understanding of factor analysis is vitally important to understand current personality research. In the following, a brief overview of the most important steps is given. A far more detailed treatment of the technique and associated issues can be found in Mulaik (2010), for example.

Exploratory and Confirmatory Approaches

Factor analysis may be used with different research goals in mind. On the one end of a continuum from exploratory to confirmatory analyses, the goal may be to infer the number and relationships between latent variables underlying an empirical data set, free from any preconceived notions about the true latent structure. Exploratory factor analysis (EFA) is a form of factor analysis that is well suited for this research goal.

On the other end of the continuum, the goal of confirmatory factor analysis (CFA) is to empirically test or assess the tenability of a hypothesized latent structure for a set of observed variables. The major difference between CFA and EFA is that the latent structure has to be specified before any analyses can be done with CFA. Theoretical assumptions and previous empirical findings may be sources of knowledge to specify a factor model in advance before even the data collection begins.

Although the (common) factor model of both EFA and CFA is basically the same, there are many procedural differences that serve to accomplish the different goals of analysis. Hence, it appears to be useful to classify a factor analytic approach as EFA or CFA even when the basic model is the same and the specific goal may be located somewhere between the endpoints of the continuum. The focus of the following presentation will lean toward the EFA end because it has been the approach that is descriptively more characteristic for personality research, although this might well change in the proximate future. Terminology, issues, and problems of using the factor model in personality research will be highlighted in the subsequent sections.

Factor Model

Consistent with the presentation of the generalized model for latent variables above, the factor model can be stated in matrix notation as

$$\mathbf{Y} = \mathbf{\Lambda\eta} + \mathbf{\Psi E} \qquad [6]$$

This function is called the fundamental equation of factor analysis. The vector $\boldsymbol{\eta}$ contains the common factors that are assumed to be causal for the manifest variables and, hence, for their covariances and correlations. $\mathbf{E}$ is a vector of unique factors with expected values of zero and variances of unity. The unique factors may actually be composed of more than one latent variable and/or random errors. It is essential, however, that any latent variable that is an element of $\mathbf{E}$ is causal for only one measured variable and cannot be considered to be common for two or more manifest variables.

Common factors and unique factors are weighted by their respective factor pattern matrices $\mathbf{\Lambda}$ and $\mathbf{\Psi}$, where the former is the matrix of so-called loadings and the latter is a diagonal matrix because unique factors are assumed to be uncorrelated. Since common factors and unique factors are uncorrelated, the correlations between manifest variables ($\mathbf{R}_{YY}$) are only due to (1) correlations among the common factors, noted as $\mathbf{R}_{\eta\eta}$, (2) regression coefficients of common factors and manifest variables, noted as $\mathbf{\Lambda}$, and (3) the squared factor pattern vector of unique factors, $\mathbf{\Psi}^2$. Taken together, this equation is known as the *fundamental theorem of factor analysis*:

$$\mathbf{R}_{YY} = \mathbf{\Lambda R}_{\eta\eta}\mathbf{\Lambda}' + \mathbf{\Psi}^2 \qquad [7]$$

In factor analysis, the relations between the manifest variables are explained in terms of the latent variable structure. The correlation matrix of manifest variables that represents the relations entirely explained by common factors is the so-called reduced correlation matrix given in eqn [8]:

$$\mathbf{R}_C = \mathbf{R}_{YY} - \mathbf{\Psi}^2 \qquad [8]$$

Since $\mathbf{\Psi}^2$ is diagonal, the correlations between the manifest variables are unaffected by the subtraction in eqn [8]. The diagonal of $\mathbf{R}_C$ contains values that are called communalities. The communalities are the proportions of the variances of the q manifest variables that are determined by the k common factors. The communality of a single variable j is defined as the sum of its squared factor loadings in the case of uncorrelated (i.e., orthogonal) common factors, which is a starting assumption in EFA:

$$h_j = \lambda_{j1}^2 + \lambda_{j2}^2 + \ldots + \lambda_{jk}^2 \quad (j = 1, 2, \ldots, q) \qquad [9]$$

The reduced correlation matrix $\mathbf{R}_C$ is the basis for the extraction of common factors.

Extraction of Factors

The model stated in eqns [6] and [7] includes a number of unknown parameters like factor loadings, correlations between factors, and so forth. The first step in EFA is the estimation of the model parameters, also known as the extraction of common factors. The reduced correlation matrix $\mathbf{R}_C$ is the starting point for this estimation process. It should be noted that the communalities are already necessary at this point although they can be determined only when knowing at least the loadings of the model (see eqn [9]). As a result, the reduced correlation matrix $\mathbf{R}_C$ that is the starting point for the estimation process includes preliminary estimates for the communalities. The final communalities are determined after the model parameters are estimated.

The extraction of common factors can be done with a number of different statistical techniques. Only two of the

most prominent approaches can be described briefly here: the principal axes and the maximum likelihood method.

The essence of the principal axes method in the common factor model is the calculation of factors that explain a maximum of the variance of the manifest variables, while minimizing the residuals. Summing up the squared factor loadings of the factor p gives the eigenvalue γ of this factor:

$$\gamma_p = \lambda_{1p}^2 + \lambda_{2p}^2 + \ldots + \lambda_{qp}^2 \quad (p = 1, 2, \ldots, k) \qquad [10]$$

When using the principal axes method, the reduced correlation matrix $\mathbf{R}_C$ is decomposed into its eigenvalues and eigenvectors, which serve as a basis to determine the factor loadings. A detailed description of the mathematical procedure can be found in the pertinent literature (e.g., Mulaik, 2010). Principal component analysis is another popular procedure at this stage of the process. There are a number of differences between principle component analysis and factor analysis as described here. Two of the important differences are that (1) principal component analysis is used with the goal to find a minimum number (rank) of dimensions that allow to reproduce a maximum of the variance in the raw scores of the variables, and, most importantly in the present context, and (2) the model of principal component is fundamentally different from the one presented in eqn [6] (for an elaborate comparison see, e.g., Widaman, 2007).

Another important method for the extraction of common factors is the maximum likelihood method. One of the fundamental differences to other methods of extraction in EFA, including the principal axes method, is that the maximum likelihood method provides statistical estimates of model parameters for a population in which the factor model is assumed to hold. When the parameters are estimated with this method, the likelihood of the observed correlations between the manifest variables, given estimates of the parameters, can be calculated. The procedure is repeated until the factorial structure for which the observed correlations have the maximum likelihood is found.

As Fabrigar et al. (1999) pointed out, both methods have several advantages and disadvantages. In contrast to the principal axes method, the maximum likelihood approach provides a statistical model test and the possibility to calculate several fit indices to assess the appropriateness of the factor model. The model test and indices may also be used for the comparison of models with different numbers of latent variables, for example. Statistical tests are also provided for the model parameters by using the maximum likelihood. One of the disadvantages of this method lies in the requirement to make the assumption of a multivariate normal distribution of the manifest variables. The principal axes method, in contrast, does not require distributional assumptions. Although the statistical tests may be rendered useless by the violation of the distributional assumption with maximum likelihood, the parameter estimates are not necessarily negatively affected in such a case.

Determination of the Number of Factors

One of the fundamental issues with regard to the latent structure is the question of how many factors there are. In the process of determining this number, two possible errors of misspecifications can occur. Firstly, overfactoring is given when the process results in a model with more factors than necessary. Secondly, underfactoring describes a result with a model that includes too few latent variables as common causes for the observed variables. In the latter case, the model is too parsimonious, that is, the preferred number of common factors is too small. With respect to the calculation or estimation of the model parameters, it appears to be advisable to avoid the error of underfactoring more strongly than overfactoring.

Arguably, the three most popular methods for the determination of the number of factors in EFA are:

- The eigenvalues-greater-than-one rule, also called the Kaiser–Guttman rule. This rule demands the extraction of as many factors as there are eigenvalues greater than one after the initial extraction of factors based on the correlation matrix $\mathbf{R}_{YY}$ instead of the reduced correlation matrix $\mathbf{R}_C$. In literature this method was often misapplied by referring to the wrong matrix (Fabrigar et al., 1999).
- A graphical procedure for determining the number of factors is the so-called scree test. Here, the size of the eigenvalues (based on $\mathbf{R}_{YY}$ or $\mathbf{R}_C$) is plotted against the number of eigenvalues in descending order, and adjacent points are connected by a straight line. The graph is inspected to identify the point where, from left to right, the slope of the connecting lines markedly levels off. The number of factors is determined as the number of eigenvalues to the left of the point identified.
- A simulation-based approach to determine the number of factors is parallel analysis. The idea is to repeatedly determine the eigenvalues in a simulation study that arise in a specific situation simply by chance. The situation in the simulation study is specified as identical in number of observed variables and respondents with the situation of interest. The average (or 0.95-quantile) of the simulated eigenvalues is computed for each ordered eigenvalue. The mean (or quantile) is then compared with the empirical eigenvalues. The number of factors to extract is given by the number of empirical eigenvalues that are greater than the simulated counterparts, because they are 'above chance.'

Because none of the methods is fail-safe, it appears to be reasonable to apply multiple criteria. Fabrigar et al. (1999) suggest using the scree test and parallel analysis in conjunction to find the appropriate number of factors. If the common factors are extracted with the maximum likelihood method, it is more natural to use the result of the model test and additional fit indexes to determine the number of latent variables. Of course, depending on where on the continuum from exploratory to confirmatory the specific approach is, theoretical plausibility may also be taken into consideration.

Identification and Rotational Indeterminacy

If a unique set of values can be determined for the model parameters, a model is said to be identified. When the number of common factors is larger than 1 in EFA, this is not the case. This so-called rotational indeterminacy alludes to fact that different sets of loadings in the model may be chosen that cannot be distinguished with respect to their quality of

reproducing the correlation matrix $\mathbf{R}_{YY}$. It is also possible under rotational indeterminacy to choose a transformed set of loadings without changing the factor model equation fundamentally. Suppose that eqn [6] with extracted factors may be written as $\mathbf{Y} = \mathbf{\Lambda}^*\boldsymbol{\eta}^* + \mathbf{\Psi}\mathbf{E}$. This equation may be modified as

$$\begin{aligned} \mathbf{Y} &= \mathbf{\Lambda}^*\mathbf{M}\mathbf{M}^{-1}\boldsymbol{\eta}^* + \mathbf{\Psi}\mathbf{E} = \mathbf{\Lambda}\boldsymbol{\eta} + \mathbf{\Psi}\mathbf{E} \\ \text{where } \mathbf{\Lambda} &= \mathbf{\Lambda}^*\mathbf{M} \\ \text{and } \boldsymbol{\eta} &= \mathbf{M}^{-1}\boldsymbol{\eta}^* \end{aligned} \qquad [11]$$

Hence, there is an infinite number of $k \times k$ transformation matrices $\mathbf{M}$ that may possibly be used for adjustment of the common factors (see also Mulaik, 2010: 275 ff.). Prima facie, rotational indeterminacy may appear to be a fundamental problem of EFA but, in fact, it is actually productively exploited by most researchers when the matrix of loadings is transformed to arrive at a solution that is more interpretable.

In most cases this means to target a solution where (1) every common factor shows high factor loadings on a subset of manifest variables and low factor loadings on the remaining manifest variables, and (2) every manifest variable shows high loadings on a very small number of common factors. Such a structure would roughly be called a simple structure.

A fundamental question that has to be answered when rotating factor loadings is whether the factors are forced to remain uncorrelated or not, that is, whether $\mathbf{R}_{\eta\eta}$ is forced to remain diagonal or not. Orthogonal rotation techniques provide factor models whose factors are forced to be uncorrelated whereas oblique rotation techniques allow correlations between common factors.

There are numerous available rotation techniques, both orthogonal and oblique (for a systematic overview, see Browne, 2001). Fabrigar et al. (1999) pointed out that oblique rotation techniques do not necessarily provide high correlations between common factors. If latent variables are uncorrelated in the population, oblique rotations will give solutions with correlations close to zero. For that reason, the use of oblique rotations seems advisable in EFA.

The last step in EFA after rotation is the interpretation of the common factors. The interpretation is based on the mathematical properties of the factor model and on the meaning of the set of manifest variables that show high loadings on the same factor. For the purpose of interpretation the researcher may refer to the factor pattern matrix and to the factor structure matrix. Both matrices contain information about the relationships between the factors and the manifest variables of the model. The factor loadings $\mathbf{\Lambda}$ are regression weights that apply when predicting the observed variables from the common factors. They can be found in the factor pattern matrix. The factor structure matrix contains the covariances between the manifest variables and the factors. If all variables are standardized, as is customary in EFA, this matrix shows the correlations between indicators and latent variables. If the final factor model evinces a simple structure, this will be reflected especially in the factor pattern matrix. Only if an orthogonal rotation was conducted or an oblique rotation results in orthogonal factors, the factor pattern and the factor structure matrix would be identical.

Blurring the Distinction between EFA and CFA: Recent Developments

A vast number of useful extensions and enhancements of the basic factor model as presented has been published, including nonlinear, longitudinal, and even meta-analytic factor analysis, for example. Two of the more recent developments are highlighted here to illustrate how progress with the method has been fruitful for personality research. Both developments are indicative of the gradually becoming more fuzzy distinction between confirmatory and exploratory factor analytic approaches.

Firstly, stepwise exploratory factor analysis (SEFA; Kano and Harada, 2000) is a method that enhances the use of EFA for scale construction in personality research by providing a means for variable selection that helps to improve the fit of the factor model. SEFA is focused on the model fit, an aspect that is of utmost importance in confirmatory approaches, but it helps to improve fit by the elimination and addition of observed variables in a stepwise fashion. An example of the use of this method in personality research is given by Schulze and Roberts (2006).

Secondly, exploratory structural equation models (ESEM; Asparouhov and Muthén, 2009) is a method that helps to overcome the need for strict loading restrictions in CFA that often lead to factor models with an inadequate fit to personality item data. In contrast to SEFA, the data basis is not altered with ESEM. Instead, the loadings as model parameters in particular are more flexibly determined than is common in CFA by reintroducing rotational techniques into the confirmatory approach. An example of the application of ESEM using the big five model of personality is given by Marsh et al. (2010).

Overall, both approaches exemplify different methods between the endpoints of purely EFA and CFA. It appears that for personality research as it has been done for more than a century, such approaches may lead the way to enhanced instruments and models.

Synopsis

The (exploratory) factor model serves as an example for a special latent variable model which can be integrated in the framework of the generalized linear model for latent variables. For all models that include latent variables, the following steps have to be considered: (1) specifying the mathematical model, (2) estimating the model parameters, (3) (when possible) evaluating the fit of the model, and (4) interpreting the results. For EFA, these steps were briefly described above while taking into account that the EFA framework has special characteristics. That is, based on the choice of estimation method, the fit of the model is not always evaluated (e.g., with principal axes extraction). In addition, due to the issue of rotational indeterminacy, the factor loadings can be transformed to satisfy the need for a better interpretation of the loading pattern. Used with great care and understanding of the statistical theory, EFA can identify the structure of latent variables that explain the correlation of manifest variables. For more information about factor analysis see, for example, Mulaik (2010). For more information about the generalized linear model for latent variables, see Skrondal and Rabe-Hesketh (2004).

False Memories

Rebecca M Nichols, Daniel Bogart, and Elizabeth F Loftus, University of California, Irvine, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Our memories are not always the perfect representation of past events. We are certainly prone to forgetting, but somewhat less obviously, our memories are also susceptible to distortion. We are even capable of developing whole, new memories that are entirely false. False memories have consequences for people in their daily lives. Scientists have studied false memories in a laboratory setting in order to understand how they develop. Here, we describe various research methodologies and theoretical explanations for false memory phenomena.

For many of us, the experience of forgetting where we put our keys or where we parked our car is an all too familiar one. What routine occurrences such as these illustrate is that our memory system is not perfect: forgetting occurs quite frequently. Forgetting is a process that is uncontroversial. In contrast, other types of memory errors are less intuitive. Unlike errors of omission, which involve forgetting, errors of *commission* involve the incorporation of incorrect information into our memories. On one end of the continuum, false memories can involve the addition of incorrect details, such as misremembering the friend that was with you when you learned about the attacks of 11 September 2001. On the other end, false memories can be for entire events that never occurred, such as being lost in a shopping mall or attacked by an animal as a child.

What do false memories look like? For one thing, false memories are typically accompanied by the belief that the remembered information is true. False memories sometimes go beyond merely having mistaken beliefs about the past. One of the most common distinctions that memory researchers draw when assessing memory is between 'remembering' and 'knowing.' For example, in some studies, people memorize word lists and later are tested on them. During the memory test, people are probed about whether they merely have a sense that the word had been presented before (i.e., they *know* they have seen it before), or whether they actually have a distinct memory of having seen it before (i.e., they *remember* seeing it). Full-fledged false memories are accompanied with a real sense of recollection of the event in question, not merely the general sense that an event occurred.

How do we know false memories exist? Decades of research and real-world examples serve as proofs. If, at this point, the idea that false memories exist as a common occurrence seems surprising, let us turn to a few quick tests we can take to support the notion. Firstly, many, if not all, of us have had the experience of recalling some shared memory with a friend or family member, only to find out that there were major inconsistencies between the two accounts. In instances such as these, where both accounts cannot be simultaneously correct, at least one party must be experiencing a false memory (assuming both are being honest about what they remember). As a separate, but related, type of situation that demonstrates the existence of false memories, perhaps some of you have had the embarrassing experience of recounting an exciting memory of some personal experience you had only to have the person listening to you exclaim that he or she was the one whom that happened to, not you!

In addition to instances such as these, in which there are two or more conflicting memories for the same event, there are some details of individual memories that we can introspectively observe as not possible to be true. To see this, think back to a memory you have from your early years. Take a moment to visualize the scene, and try to visualize as many details as you can. Here's the test: when picturing the scene, where is your vantage point? In other words, are you seeing the event from the perspective of where your eyes were looking at the time, or do you have a more zoomed out view, looking upon your younger self from the perspective of a third party? Autobiographical memories with this latter quality (called the *observer perspective*, as opposed to *field perspective*) are clear examples that memories do not remain stored in the exact way they are initially experienced.

Our memory system does not operate in the same way as a DVD, loyally and comprehensively storing an objective recording of past events. Rather, details for the past can be distorted in a number of ways. These distortions can happen as a result of many causes, such as: viewing and incorporating photographs of past events into memory; discussing past events with others; vividly imagining events or event details that later get confused with the original memory; suggestive questioning used in interviews and therapeutic techniques; and cognitive, emotional, and motivational biases, to name a few (for more on laboratory experiments that examine these factors, see the Studying Memory Distortion section).

Here we review some instances of false memories that have occurred in the real world. Next we dissect some of the techniques and methodologies used to study false memories in laboratory settings, and what those experiments have demonstrated. Subsequently, we review some theoretical accounts regarding why false memories occur, and what factors contribute to a person being more or less susceptible to their development.

False Memories in the Real World

False memories occur to varying degrees in real world and in everyday life. In the broadest sense of the term, false

memories refer to instances when we get certain aspects of remembered events wrong. This might happen when we misremember how a movie ended, or who attended last year's Thanksgiving dinner. These types of false memories for details can (and do) happen while overall memory for the general event – i.e., seeing a movie, and getting together for a Thanksgiving dinner – remains intact. But even general memories for autobiographical events are, at times, fallible. The richest, most robust forms of false memories involve just such instances of memory error; not only do we sometimes forget that entire events occurred, but we also sometimes remember whole events that never did (for more on this phenomenon, *see* Confabulation).

In the real world, memory errors such as forgetting or mixing up details of past events happen quite frequently. These errors are typically innocuous, and often go unnoticed or uncorrected in the social situations in which they are recounted. From a functional standpoint, some researchers have argued that this makes complete sense, as a primary purpose of using memory to tell stories, for instance, might not be the accuracy of the account, but rather its entertainment value or a transmission of cultural or group values (Newman and Lindsay, 2009; Levine et al., 2009). Regardless of whether or not such a flexible memory system might serve some overall adaptive purpose, real-world examples of memory errors have, at times, devastating repercussions.

False memories for details of criminal events, for example, occur in cases of mistaken eyewitness identification. One contributing factor to false eyewitness memory involves a process called *unconscious transference*. In cases of unconscious transference, an eyewitness inadvertently confuses the memory of the assailant's appearance with that of another person, perhaps a bystander or other innocent person who was seen around the time of the crime. In one particularly ironic demonstration of this effect, a psychological expert in the field of eyewitness testimony was accused of rape by a victim who had seen a TV interview in which the psychologist was featured (Schacter, 1996)! Luckily, the expert had an airtight alibi in this instance and was able to prove his innocence, but such is not always the case. In fact, according to the Innocence Project, eyewitness misidentification is the number one contributing cause in cases of wrongful conviction, implicated in nearly 75% of such cases (Eyewitness Misidentification, 2012). The point of these examples is that false memories in the real world can have devastating effects.

While false memories can and do develop naturally, sometimes their formation is facilitated by other factors such as social manipulation (purposeful or otherwise), or even genuine efforts to treat those who are psychologically distressed. As an example of the former, when police officers provide positive feedback after an eyewitness identifies a suspect from a lineup, the confidence in the witness's selection can become inflated to a level well beyond what it would have been otherwise, and one that is wholly independent of the memory's actual veracity. This is what happened to a woman named Jennifer Thompson, who received just such feedback from law enforcement officers after she misidentified Ronald Cotton as the man who had raped her. The consequences were dire for all parties; Cotton spent 11 years of his life in prison before being exonerated by DNA evidence and Thompson has had to grapple with the fact that she identified an innocent man. For a personal account of the story from Thompson-Cannino et al. (2009), see the book they coauthored entitled *Picking Cotton* and *see* Eyewitness testimony for more information about the psychological implications of witnesses' accounts.

False memories have also been created by the use of questionable therapeutic techniques. Fanning the flames of this controversy, these memories were not for mundane events such as brushing one's teeth or getting a haircut, but rather for highly emotionally charged episodes of child sexual abuse. During the late 1980s and early 1990s the number of people coming forward with such 'recovered' memories of child sexual abuse was staggering. Self-help books such as *The Courage to Heal* asserted bold claims like: "if you think you were abused and your life shows the symptoms, then you were" (p. 22). Operating under similar assumptions to those found in books like this, some therapists employed techniques like hypnosis in order to relax the patients and relieve them of their psychological defenses, thus freeing them to remember long forgotten episodes of abuse.

Or so the story goes. In what has been dubbed the most contentious debate in the history of psychology, the 'memory wars' were a vitriolic argument over whether techniques common to clinical settings were leading to high rates of false memories in therapy patients (Diamond, 1980; Spanos et al., 1999). Some scientists examined these suspicious techniques in laboratory settings. One technique that has been considered problematic is a type of 'guided imagination.' Several studies have shown that imagining that an event took place makes it more likely that people come to believe that the event actually did take place, a phenomenon called 'imagination inflation' (Garry et al., 1996; Thomas and Loftus, 2002). Because hypnosis is often paired with instructions to imagine certain events occurring, and because it leaves the person in the hypnotic state particularly vulnerable to suggestion, it brings with it the real risk of creating false memories.

What resulted from these practices were hundreds of patients who entered therapy and left with newly 'recovered' memories of past abuse. Believing that they had been abused as children, men and women began litigating against their parents, or former neighbors, or teachers or others whom they now believed had abused them. In one case, a man named Paul Ingram was accused first by one of his daughters, Ericka, and later by his other daughter, Julie, and eventually one of his sons, Chad, of having inflicted just such abuse over a decade prior. Ingram and his family were devoutly religious and regularly attended church. Ingram was also a cop. As time progressed, the content of accusations against Ingram got more and more grisly; they included claims from Julie that her father and some of his fellow cops regularly raped the daughters after their weekly poker games. When first asked whether satanic rituals had occurred, Julie replied that they had not. Months later, however, Julie remembered more details: she now recalled being burned with scalding irons and being cut with knives so blood could be obtained for sacrificial rituals (Watters, 1991).

Initially Paul Ingram had no memory of any of these occurrences, but he asserted that he had raised his daughters to

tell the truth, and reasoned that what they were saying must be true. Over time, and with the suggestion of interrogators and his pastor, Ingram also began 'remembering' taking part in these satanic sex rituals. Despite the mounting reports and the confession from Ingram, many of the details of the case still were not adding up. In order to resolve some of the inconsistencies, the prosecution brought in psychologist Richard Ofshe, an expert on cult practices. While interviewing Paul Ingram, Ofshe became skeptical and decided to test Ingram's reliability. In order to do so, Ofshe invented a piece of evidence and asked Ingram if he remembered it: *your son and daughter said that you forced them to have sex with each other while you watched*. Consistent with the pattern observed to this point, Ingram at first had no recollection of this, but after praying on it for a few days, the memory came to him and he confessed that he had, in fact, orchestrated such abuse. Neither son nor daughter corroborated this claim.

As this case progressed, physical evidence – which would be expected given the scope and regularity of the supposed cult rituals taking place – was noticeably absent. It became clear to many that the details were too outlandish, and the discrepancies too large to be believed. Paul Ingram eventually realized that his confessions had not been based on true memories, but were rather the result of suggestion and imagination. This realization came, however, after he pled, and was found to be, guilty of the crimes. Unfortunately, as is often true in cases of false confession (where a person confesses to a crime he did not commit), the confession is so powerful that it contaminates how the other pieces of evidence are evaluated (Kassin et al., 2012). Cases like these, centered around false confessions, ruin lives and waste thousands of dollars in resources.

The cases involving Ronald Cotton/Jennifer Thompson or Paul Ingram illustrate an important point: false memories can have potentially dire consequences in real-world settings. This is true whether they involve errors in memory details, such as the face of the perpetrator in the Cotton/Thompson case, or the remembering of entire events that never occurred, such as with the Paul Ingram case. Ingram shows us that false memories can even lead a person to internalize beliefs of guilt and confess to a crime he never committed. In light of the important consequences that false memories can have, it is crucial to view memory skeptically and explore the roles that suggestion, imagination, and other techniques such as hypnosis play in increasing the likelihood that they develop.

Studying Memory Distortion

Over the course of the last few decades, researchers have been able to demonstrate that that our memories do not always operate as reliably as we would like them to. Memory does not work like a DVD or video recorder; we instead construct and reconstruct our memories, and it is during this process that memories may become susceptible to damage and distortion. For more than 40 years, psychological scientists have created false memories in human subjects using an assortment of clever techniques. These tactics vary tremendously in their methods and styles, and because of this, the memories that develop from each of them take on very distinctive qualities.

Early memory distortion work examined the effects of question wording on subsequent memory reports. For example, Loftus and Palmer (1974) showed subjects a video of an automobile accident. Afterward, some subjects were asked "How fast were the cars going when they hit each other?" while other subjects received the same question but with 'bumped,' 'contacted,' 'collided,' or 'smashed' written in place of 'hit.' Subjects' estimates of speed varied depending on the verb used in the question: subjects who read 'bumped,' for example, estimated a slower speed on average than subjects who read 'hit,' who reported a slower speed on average than the subjects who read 'smashed.' Subjects who read 'smashed' were also most likely to report having seen broken glass in the video, though no broken glass was ever present. The wording of the question seemed to imply something about the content of the video itself, and this, in turn, affected subjects' memory for the witnessed event.

The smashed-hit study shows that a leading question can affect the answer a witness gives and also affect their memory. But other forms of suggestion can also affect witness memory, particularly when the suggestion contains misinformation. Misinformation can impair a witness's memory for the details of an event, a phenomenon, which is now known as the 'misinformation effect' (Ayers and Reder, 1998; Loftus, 2005). In a typical misinformation effect study, subjects witness some type of event, are later given some misleading information about that event, and then are tested on their memory for original event details. In one study, subjects viewed a series of slides that depicted an automobile accident. Afterward, the subjects were given some misinformation about the event. For example, some subjects were asked "Did another car pass the red Datsun while it was stopped at the yield sign?" though the car was actually stopped at a *stop sign* in the slideshow. When subjects' memories were tested for elements from the original slideshow, those who received the misinformation were more likely to report having seen a yield sign than those who did not (Loftus et al., 1978). Research on the misinformation effect has persisted for more than 30 years, and researchers continue to produce the effect in slideshow events (Okado and Stark, 2005) as well as video events (Takarangi et al., 2006) and live events (Morgan et al., 2013). The misinformation effect is particularly useful for understanding factors that can influence eyewitness memory; eyewitnesses may be exposed to incorrect details about a crime or other witnessed event from cowitnesses, law enforcement officers, or other legal professionals (Wright et al., 2009). To the extent that witnesses encounter misinformation from these and other sources, their memories may be in jeopardy, and this can have profound consequences for legal outcomes and for justice.

Another widely studied false memory research paradigm is known as the Deese–Roediger–McDermott (DRM) list-learning task (Roediger and McDermott, 1995; Stadler et al., 1999). In the DRM, subjects attempt to memorize lists of semantically related words (e.g., *note*, *sound*, *piano*, *sing*, *radio*, *band*, etc.). Afterward, subjects' memory is tested for studied words (e.g., *note*), nonstudied, nonrelated control words (e.g., *pocket*), and, importantly, nonpresented but semantically related critical items (e.g., *music*). At test, subjects recognize having studied these critical items at substantially large rates. Critical

items can also be freely recalled (Gallo, 2010). The type of errors produced by the DRM truly shows the associative nature of our memories: we may be at risk for holding a false memory if it seems to fit in *schematically*, or within the overall mental representation, of a true memory.

One criticism of the misinformation and especially of the DRM studies, however, is that they operate within the confines of a highly restrictive laboratory environment. It has been argued that because they do not closely approximate real-world situations, they therefore do little to explain how memories can be distorted for perceptually rich, personally relevant, meaningful autobiographical events. Some have even decried the use of the term *false memory* to describe the type of errors that the DRM tends to produce (DePrince et al., 2004; Freyd and Gleaves, 1996). Researchers have also been able to demonstrate, however, that memories from our own past can be created in experimental settings. In the first of these studies, Loftus and Pickrell (1995) led approximately one-quarter of subjects to believe, over the course of three interviews, that, as children, they had been lost in a shopping mall and rescued despite confirmation from their family members that this had never actually happened. Since then, other types of these rich false memories have been planted, such as spilling punch at a wedding (Hyman et al., 1995), suffering from a vicious animal attack (Porter et al., 2000), and getting sick after eating boiled eggs or dill pickles (Bernstein et al., 2005). A plethora of techniques for creating rich false memories has been developed over the years, which include dream interpretation (Loftus and Mazzoni, 1998), guided visualization (Paddock et al., 2000), hypnosis (Spanos et al., 1999), false feedback (Bernstein et al., 2005; Laney and Loftus, 2008), doctored photographs (Wade et al., 2002), doctored video (Nash and Wade, 2009), and guided imagination (Garry et al., 1996).

Despite the large assortment of rich false memory techniques developed, false autobiographical memory research has not come without criticism. Some have claimed that the memories that result from typical laboratory-based experiments are plausible and therefore relatively easy to accept as true events from one's past (Pezdek and Blandón-Gitlin, 2011). It may be difficult, therefore, to apply the results of these studies to explain high-profile repressed memory cases such as the Paul Ingram case. However, events with somewhat low plausibility (such as receiving an enema in childhood) and even extremely low plausibility (such as a seeing a ghost) have been successfully planted in experimental subjects (Sharman and Scoboria, 2009, 2011), and this suggests that memory distortion processes could also be at work in cases of repressed memories of highly unusual or improbable events.

The scientific psychological literature is replete with techniques developed to induce the formation of false memories. The memories that result vary wildly in terms of their complexity and meaning: a false memory from the DRM does not possess the richness and personal significance of a false memory from one's childhood. When taken together, however, the corpus of scientific false memory manipulations shows just how malleable our memories can be, and they help address questions about how and under what conditions our memories can be distorted.

False Memory Theories

Given the prevalence of false memories in controlled research settings and in the real world, it is useful to understand the theoretical explanations for false memory phenomena as a means for understanding why false memories develop and how we can potentially predict them in a number of circumstances.

Perhaps one of the first theoretical contributions to explain false memory formation arose from the work of Bartlett (1932), who began to distinguish *reproductive* from *reconstructive* memory processes. Reproductive processes operate similarly to playing back recorded video; they produce memories that are accurate representations of the material that was encoded. Reconstructive processes, on the other hand, involve a mixture of accurately recalled material from the original event as well as an active rebuilding of the missing pieces. The resultant memory can be, therefore, a combination of both accurate and inaccurate details. Bartlett believed that reconstructive processes were more likely to take place when recalling events that were particularly lengthy or detailed. Bartlett's musings, which bucked the trend at the time about how memory works, continue to weave their way through contemporary theories about memory generally and false memory in particular.

As scientists began to move away from thinking about memory recall as pushing 'play' on a recorded video, false memory theories became more refined. For example, Underwood (1965) first proposed an associative theory of false memory. His implicit associative response theory states that we all hold semantic networks, or webs of information with nodes (concepts) that are connected to other semantically related nodes. The strength of these connections depends on the relatedness of the items and the frequency with which those items are activated. For example, in a word-list task, subjects may be asked to memorize the word 'sleep.' Implicitly, or without conscious awareness, subjects may simultaneously activate the node that represents 'bed.' Underwood found that when tested, subjects were more likely to falsely remember nonpresented words if they were semantically associated to the target word. More generally, associative strength has important implications for memory reconstruction: to the extent we are missing pieces of a memory but have activated related items, we are at serious risk for reconstructing our memory with schematically consistent errors of commission.

Another predominant explanation for false memory phenomena is that of Fuzzy Trace Theory (Brainerd and Reyna, 2002). This theory states that when we encode events, we encode two separate but parallel components of the event: a broad, general, overall 'gist' meaning of the event and specific, precise, 'verbatim' representations of event components. While both gist and verbatim traces both support true memory recall, false memories can arise when we properly encode the gist trace but encode the verbatim traces less well. Information from the gist is then used to fill in gaps in our memory for specifics about the event.

Activation theories and Fuzzy Trace Theory support false memories that develop spontaneously from mental processes within the rememberer. But what causes false memories to form in the presence of some kind of stimulus, such as a suggestion

about an event? One of the most widely accepted theories to explain these kinds of false memories is source-monitoring theory (Johnson et al., 1993; *see* Source Monitoring). According to this theory, subjects encode both the original event, such as the stop sign in the slideshow event from the early Loftus et al. (1978) misinformation study, and the suggestion, such as the yield sign present in the suggestive questioning about that event. False memories occur when subjects misattribute the source of the misinformation to be the original event and not the actual source of the suggestion. As described, source-monitoring theory is directly applicable to studies demonstrating the misinformation effect. However, this theory can also help explain false memory development when the suggestion is generated internally. In an imagination inflation exercise, for example, subjects are asked to rate the confidence they have that a number of events happened to them during childhood. They are then asked to imagine a selected event, in full perceptual detail, after which they are asked to rate their confidence again for all events. An increase in confidence from preimagination to postimagination may reflect the development of a false memory for that event (Garry et al., 1996). Source-monitoring theory would predict this phenomenon; for subjects who experience an increase in confidence, they might be misattributing the source of the imagined event to be their own childhood and not a recent imagination experience.

Components of multiple theories have also been combined to account for false memories in particular paradigms. For example, Roediger et al. (2001) proposed activation-monitoring theory to explain false memories that are brought about in the DRM task. This theory assumes that unstudied but associated critical items (like *music*) are activated during encoding, and monitoring processes during retrieval affect how critical items are misremembered at test. In other words, subjects may misremember *music* because they remember the slideshow as the source of the word rather than as a product of their own internal activation.

These false memory theories serve an important purpose for false memory research: they help address questions about the mechanisms that can ultimately distort our memories. Advancing knowledge about why false memories occur not only furthers our understanding about real world and lab-based false memories alike, but they can also help scientists predict when and under what conditions memory distortion is likely to develop in the future. This sort of prediction is no easy feat, but as false memory theories become more refined, so too will our understanding of false memory phenomena.

False Memory and the Brain

False memory research conducted within the last few years has spanned a number of useful and interesting topics. For example, technological advances in brain imaging have allowed researchers to examine how different behaviors or behavioral patterns might also be associated with different patterns of brain activation. In one study, researchers were curious as to whether or not there would be unique brain activation patterns for true memories when compared to false memories; if so, neuroimaging tools could be a worthwhile means for distinguishing true and false memories in different contexts. In the study, researchers subjected participants to a typical misinformation paradigm while information about brain activity was captured by a functional magnetic resonance imaging (fMRI) machine. These fMRI scanners are able to acquire patterns of blood flow in specific areas of the brain at different points in time, and where there is increased blood flow, there is increased activity of neurons. In the study, subjects were presented a visual slideshow of events and were later provided with a narrative of the event, presented aurally, that contained misinformation. When the subjects' memories were tested, true memories and false memories produced relatively similar patterns of activation, though true memories of the event (which was presented visually) were accompanied by more activation in the visual cortex while false memories (which were derived from there misinformation presented aurally) were accompanied by more activation in the auditory cortex (Stark et al., 2010). Despite this promising early work, we are a long way away from being able to take an individual memory and reliably determine whether it is true or false based on neural activity.

Final Remarks

As we have seen, memory is quite malleable. While it serves us well, our memories are probably filled with not only truths but also some fictions: small ones and large ones. Sometimes these do not matter very much, as when we tell a friend we had chicken last night instead of fish. But at other times, false memories can be devastating for the lives of innocent people. Scientists are passionate about understanding false memories, not only for the sake of scientific discovery, but also with the hope that this work will lead us to new ways to reduce the false memory problem.

Abstract

Most human characteristics (including behavioral and neurocognitive phenotypes) are influenced to some extent by heritable genetic variation. The concept of heritability, which is a measure of the relative amount of observed phenotypic variance that is attributable to genes, has had a long and controversial history in human genetics. Inference about heritability obtained from familial relationships predated and informed the discovery of the cellular and biochemical mechanisms of inheritance. Our recent ability to obtain complete DNA sequence of individual genomes reveals the full extent of human genetic diversity, and allows for identification of empirical patterns of kinship when family structure is unknown. In this context, the tools of statistical genetics remain essential for quantifying, identifying, and interpreting causal relationships of genetic variation to traits of interest. This article reviews key concepts and controversies in statistical genetics and introduces recent advances in efficient inference from complex pedigrees.

The broad strategy of human genetics is to characterize heritable genomic variation that contributes to the correlation between relatives for traits of interest, as a tool for revealing the biological mechanisms underlying these traits. This strategy is both simple and complex. It is simple because an individual's genome is a sample of each of its parental genomes via cellular processes that are well understood: the set of possible causal variation is large but finite. It is complex because we expect most traits to be the net result of variation in multiple genes whose expression is modulated by environmental exposures, and also because, for ethical and practical reasons, our initial investigations must be observational rather than experimental. Statistical genetics provides the framework for these initial investigations to define focused hypotheses that *are* amenable to experimental pursuit, and it also accounts for the effects due to genetic relatedness (which often may not be the primary focus) when interpreting experimental results. Because the strategy is both simple and complex, the tools of statistical genetics must be correspondingly both parsimonious and extensible.

Introduction to Statistical Genetics and the Heritability Concept

Human statistical genetics begins with the linear variance components (VCs) model developed by Fisher (1918) (Hopper, 1993; Hopper and Visscher, 2005). Since Fisher (1918), a dominant theme in statistical genetics has been the partitioning of the total phenotypic variance initially into uncorrelated genetic and residual environmental VCs, where the genetic variance may be further partitioned into additive, dominance, and epistatic VCs (i.e., reflecting the incremental contribution of alleles, interaction between alleles, and interaction between genes). To the extent that putative environmental causes are measurable, VCs for similarity of environmental exposures and genotype–environment interaction (GEI) may be added to the model as appropriate to clarify the genetic signal. From the genetic VCs, we get the broad-sense and narrow-sense heritability, which are respectively defined as the ratio of the total genetic variance to the total phenotypic variance, denoted by H^2, and the ratio of the additive genetic variance to the total phenotypic variance, denoted by h^2. If the dominance and epistatic VCs are negligible, then the broad-sense and narrow-sense heritabilities converge.

The simplest form of the VCs model makes the following four assumptions common to all linear models: (1) observations are normally, and (2) independently distributed, (3) effects are additive, and (4) the variance is constant or homogeneous across observations. We contend that all the major criticisms of heritability estimation (Capron and Vetta, 2001; Vetta and Capron, 2001; Vetta and Courgeau, 2003/2004) can be addressed by noting that the respective targets of the criticisms are departures from the assumptions of the simple model that can easily be accounted for by existing modeling approaches. Fisher (1918) himself initiated this approach when he extended the basic model to account for assortative mating, which is a source of nonindependence due to correlated mating behavior, and for dominance and epistasis, which are respectively nonadditivity of alleles within loci and nonadditivity among loci. Reviews of VCs models that include such extensions and more can be found in Hopper (1993) and Hopper and Visscher (2005). In the case of dominance and epistasis, however, recent authoritative reviews have concluded that such departures from nonadditivity in most cases can be considered negligible (Hill et al., 2008; Crow, 2010). Similarly, Hill (2010) observed that in genomewide association studies (GWAS) of 10 000 or more individuals, none of the identified variants showed evidence of dominance or epistasis. Because of space limitations, we cannot adequately address how violations in the assumptions of the VCs model may be accounted for. Suffice it to say that we take the position that while the VCs modeling approach can easily account for departures from its basic assumptions, it often is not empirically warranted to do so.

The mathematical formulation of the VCs model for a phenotype vector is given as follows (Blangero et al., 2001, 2013; Almasy and Blangero, 2010):

$$\mathbf{y}_{n\times 1} = \mathbf{X}_{n\times j}\boldsymbol{\beta}_{j\times 1} + \mathbf{g} + \mathbf{e}, \quad [1]$$

where $\mathbf{y}$, the phenotype vector of interest, $\mathbf{X}$, a design matrix of covariate effects, and $\boldsymbol{\beta}$, a vector of regression coefficients, are of dimensions $n \times 1$, $n \times j$, and $j \times 1$, respectively, and n and j give the numbers of individuals in the pedigree and of fixed-effects parameters, respectively; and $\mathbf{g}$, and $\mathbf{e}$ are unobserved vectors of random genetic and environmental effects, respectively. On assuming that the genetic and environmental effects are uncorrelated and that dominance and epistasis are negligible, the polygenic model for the phenotypic covariance matrix is as follows:

$$V[\mathbf{y}] = \boldsymbol{\Sigma} = \sigma_{\mathrm{p}}^2\left[\mathbf{K}h^2 + \mathbf{I}\left(1 - h^2\right)\right], \quad [2]$$

where $\mathbf{K}$ is a genetic relationship kernel or matrix (GRK), the elements of which are relatedness coefficients for individuals i and j, $\mathbf{I}$ is the identity matrix, and $h^2 = \frac{\sigma_{\mathrm{g}}^2}{(\sigma_{\mathrm{g}}^2+\sigma_{\mathrm{e}}^2)} = \frac{\sigma_{\mathrm{g}}^2}{\sigma_{\mathrm{p}}^2}$ is the standard additive genetic heritability, where σ_{g}^2, σ_{e}^2, and σ_{p}^2 are the additive genetic, residual environmental, and total phenotypic variances, respectively. For this basic model, $\mathbf{K} = 2\boldsymbol{\Phi}$, where $\boldsymbol{\Phi}$ is the expected kinship matrix generally derived directly from pedigree information. Assuming that the trait follows a multivariate normal (MVN) distribution, the model ln-likelihood function is given as follows:

$$\ln L(\boldsymbol{\theta}|\mathbf{y},\mathbf{X}) = -\frac{1}{2}\left[N \ln 2\pi + \ln\left|\sum\right| + \boldsymbol{\delta}'\sum^{-1}\boldsymbol{\delta}\right], \quad [3]$$

where $\boldsymbol{\theta} = [\boldsymbol{\beta}, \sigma_{\mathrm{p}}^2, h^2]'$, which denotes the parameter vector, is expressed as conditional on the data made up of $\mathbf{y}$ and $\mathbf{X}$, and $\boldsymbol{\delta} = \mathbf{y} - \mathbf{X}\boldsymbol{\beta}$ is the vector of residuals. The likelihood function is required for inferential procedures, including estimation of model parameters and model likelihoods via maximum likelihood (ML), and hypothesis testing by way of the likelihood ratio test (LRT) statistic.

Pregenomics Phase of the Heritability Controversy

Relative to other statistical genetic concepts, the notion of heritability has received the lion's share of controversy, which conveniently can be divided into a pregenomics phase and a genomics phase. The pregenomics phase of the heritability controversy took place during a time when, for lack of detailed genomic information, complex-trait genetics was by necessity inferential rather than mechanistic. In human genetics, controversy centered on political and social inferences from genetic data, notably Jensen's (1969) argument that consistently high estimates of heritability for measures of human intelligence implied that academic performance was determined genetically and therefore not amenable to improvement by changes in education practices or social policy. This assertion was recognized widely as employing misinterpretations of heritability that agricultural geneticists already had learned to avoid (Visscher et al., 2008). For a comprehensive treatment of this phase of the heritability controversy, we refer to Sesardic (2005) and other sections of this encyclopedia (see '*See also*' section).

Although the historical context of the pregenomic controversy has passed, one aspect of the reaction to Jensen (1969) continues to inform the current debate. Lewontin (1974, 2001), a key figure for this line of thought, took the tack of rejecting the applicability of heritability estimation to human genetics on theoretical grounds. Lewontin argued (1) that nonadditive effects have a substantial effect on traits but are not reflected in heritability estimates, (2) that heritability estimates are constrained by stochastic allele frequencies and environmental exposures of the sampled individuals and therefore are study specific; in Lewontin's view, this specificity eliminated the explanatory value of the estimates, and (3) the existence of GEI renders heritability estimates under a simple model erroneous. Similar objections to heritability and VCs estimation in general have been raised by others (Capron and Vetta, 2001; Vetta and Capron, 2001; Vetta and Courgeau, 2003/2004; Vitzthum, 2003; Rose, 2006; Rende, 2004). Recent philosophical analysis of this controversy can be found in Rende (2004), Oftedal (2005), Sesardic (2005), Tabery (2009), and Downes (2010).

The first argument of Lewontin (1974) is addressed at length in the following section, as accumulating genomic data has provided evidence to clarify this long-standing theoretical concern. The second argument deserves special attention. Agricultural geneticists have long recognized that heritability estimates are sample-specific, although the range of estimates for specific traits is often remarkably similar across studies (Falconer and Mackay, 1996, pp. 161–163). By the mid-twentieth century, heritability had long been a useful tool for agricultural breeding programs, but its predictive and explanatory value for human studies was limited, as Lewontin observed. What Lewontin (1974) failed to note, however, was that heritability is useful *because* it is sample-specific: It provides an estimate of the genetic signal available in a sample – which, upon replication, identifies traits that are amenable to subsequent genetic analysis. More important, the VCs model explicitly accounts for the *within-sample* genetic and environmental correlations among study subjects (including empirical kinship among so-called 'unrelated' individuals; Yang et al., 2010, 2011a,b). In the present genomics era, when we are able to observe the full extent of human genetic diversity directly, modeling this nonindependence is essential to separate true fixed effects of genetic variants of interest from other sources of phenotypic similarity. As for Lewontin's third criticism, we have consistently found that the incorporation of GEI in the VCs model, rather than rendering the heritability estimate erroneous, in fact and to the contrary clarifies the genetic signal measured by heritability, thereby enhancing gene detection and localization (Diego et al., 2003, 2009; Vinson et al., 2008; Voruganti et al., 2011; Kent et al., 2012).

Genomics Phase of the Heritability Controversy

The genomics phase of the heritability debate followed the availability of reference sequence data from the Human

Genome Project (http://www.ornl.gov/sci/techresources/Human_Genome/project/about.shtml) and the use of high-throughput genotypic data in human genetic studies, including GWAS (Visscher et al., 2008). Briefly, GWAS analysis tests the fixed effects on a trait of interest of a large set of common genetic markers (typically, hundreds of thousands to a few million markers per genome). These markers are chosen as proxies for expected common *functional* genetic variation in nearby chromosomal regions, based on a controversial theory that common diseases should have common causes (Chakravarty, 1999). Much of the appeal of this approach is an expectation that, if genetic causes are common across population strata, their fixed effects should account for the majority of the relevant genetics of the traits of interest. Genetic analysis therefore could be carried out in 'unrelated' individuals drawn from the general population (Risch and Merkingas, 1996), the random effects of kinship, the logistically challenging family studies needed to provide these data, and the technically complex VCs models required to estimate these effects could all be avoided. Opposition to the concept of heritability shifted from the assertion that it is wrong to the assertion that it is obsolete.

Previous heritability estimates for many traits of interest remain in the literature. Following a decade of GWAS on a plethora of complex traits, it widely is found that the fixed effects of marker variants detected in these analyses usually account for a small fraction of the heritability – often *collectively* accounting for less than 5–10% of the total trait variance (e.g., height; Lango et al., 2010). Given that complex-trait heritabilities routinely are reported to be much higher than the GWA estimates, there is the problem of having to explain the 'missing heritability' (Manolio et al., 2009).

The Impact of Sequence Data

The remarkable technological breakthroughs that allowed the Human Genome Project to generate the reference sequence for the human genome have opened the possibility of affordable sequencing on a substantial number of individuals, either via exome sequencing (covering only the protein-coding regions of known genes; Abecasis et al., 2012) or that ultimate objective, whole-genome sequencing (WGS). The wealth of data now available from these studies allows, for the first time in the history of human genetics, empirical tests of statistical genetics theory, including hypotheses about the origin of 'missing heritability'.

A leading hypothesis for the explanation of the missing heritability is that much of the genetic variance for these traits is due to interactions – especially GEI or gene–gene interaction (epistasis) (Manolio et al., 2009; Zuk et al., 2012). Arguably, Zuk et al. (2012) have offered the most forceful analysis and modeling to advance the hypothesis that the incorporation of interaction terms, especially epistasis, in the model would explain the missing heritability. Zuk et al. (2012) introduced novel limiting-pathway (LP) models of epistasis, and they showed that under these models a significant portion of the missing heritability was explained. Thus, they called the gap between naïve GWA and expected heritability estimates 'phantom heritability' because the difference was never missing after all (under their argument) but rather was simply undetected because of the lack of the epistasis VC. This phantom component is really the result of contaminated estimation of the most focal heritabilities. This primarily is the result (although not explicitly acknowledged by Zuk et al., 2012) of the overreliance on twin studies and nuclear family designs that are most susceptible to the bleeding of any epistatic component into the purely additive heritability. To our knowledge, there have been at least two developments that show that it is premature to abandon the classical most parsimonious VCs model in favor of more complicated versions of the model, such as those proposed by Zuk et al. (2012).

The first development stems from the work by Visscher et al. (2006, 2007). These investigators developed a method for assumption-free heritability estimation. What they really meant is that their method did not assume fixed amounts of genetic similarity as a function of relationship class but empirically estimated the actual observed sharing of genetic material between relatives. As shown in Visscher et al. (2007) and noted in Visscher (2009) and Hill (2010), there was a linear relationship between chromosome length and per-chromosome estimates of heritability, and no evidence of nonadditivity involving loci across chromosomes.

The second development also was initiated by Visscher et al. (Yang et al., 2010, 2011a,b). Visscher, Yang, and colleagues appropriated methods from animal breeding genetics (VanRaden, 2008) to estimate an empirical GRK based on a set of genomewide SNPs in a sample of unrelated individuals. Because the GRK is estimated on unrelated individuals, its elements (i.e., the relatedness coefficients) usually are not confounded by shared familial environmental effects (Yang et al., 2010, 2011a,b; Zaitlen and Kraft, 2012). Zaitlen and Kraft (2012) simulated data using a variety of LP epistasis models of Zuk et al. as the generating models, and then they estimated heritability using the Yang–Visscher GRK. They found that the heritability estimates were not biased by the lack of an epistasis VC in the estimating model, thus refuting the claims made by Zuk et al. (2012) regarding phantom heritability. This is a direct result of relying on more distant relationships in which epistasis has little influence on expected correlations between individuals. It can be shown that this same property is effectively observed in studies of large extended pedigrees when heritability inference is limited to relatives beyond first degree (e.g., when monozygotic twins, parent–offspring, and sibling relationships are not used for heritability estimation).

Several points should be mentioned in regard to heritability estimates in samples of unrelated individuals, especially using the GRK computed under the Yang–Visscher approach. This approach is inefficient relative to pedigree-based methods requiring 5000–10 000 individuals or more to accurately estimate heritability with modest effects (Zaitlen and Kraft, 2012). In other words, this approach has little statistical power. Furthermore, although it is true that such heritability estimates will not be influenced by shared environment, they can be upwardly biased due to hidden between-group variation (i.e., population substructure) (Zaitlen and Kraft, 2012). Conversely, when calculated using standard GWA SNP panels, this approach underestimates the true heritability of the sample population because it fails to capture the genetic

variance resulting from rare sequence variation. Improved estimates can be expected, however, in WGS studies that cover the whole spectrum of common and rare alleles. Further still, we note that the GRK under the Yang–Visscher approach is potentially biased (or at least less interpretable as a measure of heritability) because their estimates allow for negative relatedness coefficients. In this regard, we suggest the GRK estimation algorithm developed by Speed et al. (2012) as it accounts for linkage disequilibrium and estimates proper relatedness coefficients.

To return to the missing heritability problem, a second hypothesis suggests that missing heritability in GWAS is due to that method's focus on common genetic variants. Opinions differ about the exact threshold separating 'rare' and 'common' variation; for the single nucleotide polymorphisms (SNPs) typically employed in association studies, variants with a minor allele frequency less than about 1–5% generally are classified as rare. In direct contrast to the 'common disease, common variant' hypothesis that informed the GWAS strategy, population genetic theory has long predicted that the majority of genomic variation should be rare (**Figure 1**; Pritchard, 2001; Pritchard and Cox, 2002). The argument is as follows: Chance mutation introduces a single copy of a variant in a single individual; that individual has a 50% chance of passing the new variant to each of its offspring; but in the absence of strong natural selection favoring the variant, its spread through the population will be slow. On the other hand, unless it has a large effect on the trait, a deleterious rare allele will not be subject to strong purifying selection that could force its allele frequency to zero. The expected result is the accumulation of mutations at essentially every nucleotide in the genome, although the number of individuals carrying a specific mutation (and thus its minor allele frequency) will remain low.

The availability of WGS provides direct evidence that, consistent with theory, most human sequence variation is rare

Figure 1 Predicted distribution of minor allele frequencies in a population at equilibrium, assuming a biologically plausible balance between mutation and selection. For a polygenic trait, the effect sizes of most variants will be small and subject to no or weak purifying selection; consequently, most variants are rare (minor allele frequency <0.05).

(Abecasis et al., 2012) – so rare that much sequence variation is effectively private (or lineage-specific). That fraction of the genome that we are most interested in, the phenotypically functional component, is even more likely to be dominated by such rare variation. In humans, rare functional variation is best studied in large pedigrees, an approach that represents an implicit enrichment strategy for identifying and studying rare functional variants. Mendelian transmissions from parents to offspring maximize the chance that multiple copies of rare variants exist in the pedigree (**Figure 2**). Alternatively, studies of unrelated individuals like those typically performed in the now-receding GWAS era that has focused only on common sequence variation never can capture more than one copy of a 'private' variant. Although there are accumulating methods to examine the joint effects of sequence variation in a gene-centric manner that may be of value in the study of unrelated individuals, a large part of human genetics will stay focused on the rapid identification of specific rare variants of moderate to large effect on disease risk because such variants more rapidly lead to functional experimental validation and causal gene discovery with all of its concomitant benefits. Thus, it is apparent that the coming WGS era of human genetics will require a return to our fundamental roots with a refocus on pedigree-based studies of human variation (Blangero, 2004; Frazer et al., 2009; Schork et al., 2009; Ott et al., 2011).

An Eigensimplification Approach for Study Designs Involving Large Families

Utilizing optimal large pedigrees for the examination of complex human phenotypic data represents a formidable statistical problem. We have developed a method that can rapidly analyze SNPs from WGS data sampled from large extended families, which is based on the spectral or eigenvalue decomposition (EVD) of the covariance matrix (Dyer et al., 2009; Blangero et al., 2013). We call this general process the eigensimplification of the likelihood function.

Assuming for convenience and with complete generality that $\sigma_p^2 = 1$, the EVD of the covariance matrix can be written as follows:

$$\mathbf{\Sigma} = \mathbf{S}\mathbf{D}_p\mathbf{S}' = \mathbf{S}\left[h^2\mathbf{D}_g + \left(1-h^2\right)\mathbf{I}\right]\mathbf{S}' = \mathbf{S}\left[\mathbf{I} + h^2\left(\mathbf{D}_g - \mathbf{I}\right)\right]\mathbf{S}', \quad [4]$$

where $\mathbf{S}$ is an orthogonal matrix of eigenvectors, and $\mathbf{D}_p = \mathrm{diag}\{\lambda_{pi}\}$ and $\mathbf{D}_g = \mathrm{diag}\{\lambda_{gi}\}$ are respectively diagonal matrices of phenotypic and additive genetic eigenvalues. Likelihood computations now can be greatly simplified by employing a linear transformation of the vector of residuals to the eigen-basis of the covariance matrix, which we denote by $\boldsymbol{\tau}$:

$$\boldsymbol{\tau} = \mathbf{S}'\delta. \quad [5]$$

Under the transformation, the likelihood of the basic VCs model is given as follows:

$$\ln L(\boldsymbol{\theta}|\mathbf{y},\mathbf{X}) = -\frac{1}{2}\sum \ln\left[1 + h^2\left(\lambda_{gi} - 1\right)\right] - \frac{1}{2}\sum \frac{\tau_i^2}{1 + h^2\left(\lambda_{gi} - 1\right)}, \quad [6]$$

Figure 2 A San Antonio Family Heart Study (SAFHS) extended pedigree ($N = 171$ individuals). Suppose the founder indicated by the red arrow harbors a private variant. It is possible that this one family can have up to 105 copies due to Mendelian transmission.

where λ_{gi} and τ_i are respectively the additive genetic eigenvalue and transformed trait for the ith individual, and the summations are taken over n. One of the virtues of this eigensimplification approach can be understood on comparing eqns [3] and [6]. Under the likelihood function of eqn [3], the requirement of the inverse covariance matrix makes the associated computations nearly intractable for large family studies and for a large number of SNPs. Large family studies translate into a large covariance matrix, which must be inverted some number of times more than the number of SNPs. This is because to find the maximum of the likelihood function, ML estimation algorithms must 'explore' via numerical iteration the complex likelihood surface, and each iteration requires a new inversion of the covariance matrix. Moreover, this computationally intensive iterative process must be performed for each SNP. Under eqn [6], however, large matrix inversion is avoided. Thus, the original complex multivariate likelihood is simplified to a sum of univariate likelihoods, and consequently all associated likelihood computations are greatly simplified. In fact, likelihood analysis of families under the eigensimplification approach is commensurate in terms of speed with that of a sample of unrelated individuals of equal size.

Another virtue of the eigensimplification approach is that it leads to elegant simplifications in the test statistics and in power analysis. This has become an extremely useful tool for understanding the efficiency of different study designs (such as twin designs versus extended pedigree designs).

The expected likelihood ratio test statistic (ELRT) for testing heritability, derived from application of eqn [6], is given as follows:

$$\begin{aligned}\mathrm{ELRT}\left[\widehat{h}^2 > 0\right] &= E\left[-2\left(\ln L(h_0^2 = 0) - \ln L\left(\widehat{h}^2\right)\right)\right] \\ &= -\sum \ln\left[1 + \widehat{h}^2(\lambda_{gi} - 1)\right],\end{aligned} \quad [7]$$

where h_0^2 and $\widehat{h}^2$ denote the heritabilities under the null and alternative hypotheses, respectively. To write the ELRT for association testing, we note the following widely used expression for the variance at a quantitative trait nucleotide (QTN), denoted by σ_q^2:

$$\sigma_q^2 = 2p(1-p)a^2, \quad [8]$$

where p and $(1-p)$ are the allele frequencies at a single genetic locus with two alleles, and a is the displacement between genotypic means. Using the eigensimplification of the MVN likelihood, we find for testing association with a DNA sequence variant at a QTN:

$$\begin{aligned}\mathrm{ELRT}\left[h_q^2 > 0 : \text{pedigrees}\right] &= E\Big[-2\Big(\ln L\left(h_q^2 = 0\right) \\ &\quad - \ln L\left(h_q^2 > 0\right)\Big)\Big] \\ &= -n\ln\left(1 - h_q^2\right) \\ &\quad + \sum \ln\left[1 + h_t^2(\lambda_{gi} - 1)\right] \\ &\quad - \sum \ln\left[1 + h_r^2(\lambda_{gi} - 1)\right] \\ &= \mathrm{ELRT}\left[h_q^2 > 0 : \text{unrelateds}\right] \\ &\quad - \left(\mathrm{ELRT}\left[h_t^2 > 0 : \text{pedigrees}\right]\right. \\ &\quad \left. - \mathrm{ELRT}\left[h_r^2 > 0 : \text{pedigrees}\right]\right),\end{aligned} \quad [9]$$

where $h_t^2 = \frac{\sigma_g^2 + \sigma_q^2}{\sigma_p^2}$, $h_q^2 = \frac{\sigma_q^2}{\sigma_p^2}$, and $h_r^2 = \frac{h_t^2 - h_q^2}{1 - h_q^2}$ are the total, QTN, and residual heritabilities, respectively, and where we express the last form of the statistic in terms of the expected statistics for the QTN-specific heritability in a sample of unrelateds, the total heritability in pedigrees, and the residual heritability in pedigrees, respectively.

The ELRTs in eqns [7] and [9] are ostensibly simpler and easier to compute than other comparable asymptotic test statistics.

Following the methods detailed in Blangero et al. (2013), we can use these ELRTs for heritability and association testing to compute their power functions. We present in **Figure 3** a schematic diagram of several relationship–pedigree structures, including monozygotic (MZ) twins, sibships, and nuclear families. An example of a large extended family is already provided in **Figure 2**. This extended family is made up of 171 individuals across 6 generations (this is an actual family from our San Antonio Family Heart Study (SAFHS) sample that has undergone WGS). In **Figure 4**, we plot at the top panel the ELRTs for three different relationship structures, namely MZ twins, nuclear families with three siblings (NF), and the SAFHS example pedigree (EP), all scaled to 250 individuals for easy comparison. At the bottom panel of **Figure 4**, we show the scaled power functions for heritability estimation for the same relationship structures. Notably, the extended-family design is most powerful in the region of the null. For heritabilities above approximately 0.47, however, the MZ twins design becomes most powerful. Our results indicate that the conventionally and widely held belief (especially among behavioral geneticists) that monozygotic twins constitute the most powerful design for estimating heritability is fundamentally incorrect in the most important part of the parameter space (i.e., in the local area of the null hypothesis). Although we are comparing the two designs, it is noteworthy that the MZ twins design also potentially suffers from confounding of genetic and shared environmental or common household effects, whereas such confounding is much less likely in extended-family designs in which the subordinate nuclear family units typically reside in different households. As mentioned previously, twin designs also suffer from being much more susceptible to biased narrow-sense heritability estimates due to contamination from epistatic components.

Figure 4 Expected likelihood ratio test statistic and power for heritability estimation. For both panels: SAFHS extended pedigree (EP) (solid line), monozygotic twins (MZ) (dotted line), and nuclear family (NF) (dashed line) all scaled to 250 individuals.

Figure 3 Some simple relationship and pedigree structures.

We examined similar study design comparisons in relation to association testing using eqn [9]. In association testing, we are estimating the heritability attributable to a given genetic marker or sequence variant. For a total heritability of 0.1, we plotted the association ELRTs for the four relationship structures, and power to detect association for the same fixed sample sizes in Figure 5. Figure 5 shows that for this fixed low total heritability and a reasonable range of QTN-specific heritabilities, power to detect associations is greatest in unrelated samples as expected. Loss of power is greatest in the extended pedigree due to the substantial correlation between subjects, however, even for this design the loss of power is low. Figure 6 shows the effect of total heritability on power to detect association for the extended pedigree. Power to detect association is influenced by total heritability with the power loss being maximized at a residual heritability of 0.50. Interestingly, power loss as seen in the ELRT is minimal both near the null region for heritability (as expected) and is somewhat counterintuitively near the maximum of heritability (at 1). Regardless, our theoretical results show little loss of power in the association analysis of even large and complex pedigrees. Furthermore, when considering the increased focus on the analysis of rare variants, power actually is substantially increased in large pedigrees due to the accumulation of multiple copies (and hence, increased genotypic variance) of rare variants incurred through Mendelian transmission in variant-harboring lineages.

Figure 5 Expected likelihood ratio test statistic and power for association testing. For both panels: Unrelateds (dotted line), nuclear family (NF) (thin solid line with open circles), monozygotic twins (MZ), (thin solid line with cross marks), and SAFHS extended pedigree (EP) (thick solid line) all scaled to 250 individuals.

Figure 6 Effect of varying the total heritability on the expected likelihood ratio test statistic and power for association testing all scaled to 250 individuals. Total heritabilities are equal to 0.1 (solid line), 0.5 (dashed line), and 0.9 (dotted line).

Some Examples of the New Genetics and a Practical Extension

In Table 1, we highlighted results from several studies that used the Yang–Visscher approach to estimate heritability under eqn [2] using an empirical GRK computed on GWA SNP data from a sample of unrelated individuals. For crude comparisons with existing heritability estimates, we also included a column for heritability estimates from twin studies. The traits shown span a wide range of interests relevant to social and behavioral scientists. Importantly, together they show that heritable genetic effects can have an unequivocal impact on overall trait variation.

The issue of common and rare variation emerges in each of these studies. Since these were, from a genetics perspective, GWA studies, they used common SNP variants. As can be gleaned from a closer examination of these results, only some

of the missing heritability was explained. For reasons given earlier in this entry, we are confident that WGS studies on families will be able to more fully recover the missing heritability.

One widely held position regarding the potential contribution that the new genetics can make to the social and behavioral sciences is that genetic data, especially of the GWA or WGS variety, may be used fruitfully as control variables (Beauchamp et al., 2011; Benjamin et al., 2012a,b; Fowler and Dawes, 2013). Just following, we outline how genetic data may be used as control variables in the context of the VCs model. Perhaps somewhat counterintuitively, heritability can be used to clarify inferences on the effect of nongenetic variables of interest to social and behavioral scientists. Let γ denote the ratio of nongenetic to genetic effects; that is, $\gamma = (1 - h^2)/h^2$. Then, the vector of estimated genetic values (EGVs), denoted by $\widehat{\mathbf{g}}$, is given as follows (Quillen et al., in press):

$$\widehat{\mathbf{g}} = \left(\mathbf{I} + \mathbf{K}^{-1}\gamma\right)^{-1}\boldsymbol{\delta}. \qquad [10]$$

Since $\widehat{\mathbf{g}}$ is the estimated version of $\mathbf{g}$ in eqn [1], it can be thought of as the genetic contribution to the phenotype. Furthermore, with this estimate we can sweep out genetic effects to obtain a derived trait that highlights environmental or, more precisely, nongenetic effects. Specifically, we can do this simply by rearranging eqn [1] as follows:

$$\widehat{\mathbf{e}} = \mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \widehat{\mathbf{g}} = \boldsymbol{\delta} - \widehat{\mathbf{g}}. \qquad [11]$$

This equation should prove useful in investigations of social and behavioral traits known to be partially under genetic influence as in those in **Table 1**.

Conclusion

As we have shown, the concept of heritability has gone, in the genomics phase of its controversial history, from being perceived as 'irrelevant' to now being recognized as a matter of central concern. This is true for at least two reasons related in different ways to the missing heritability problem. For one, we showed that the missing heritability problem stirred up interest in the consideration of more complex VCs models that include interactions (e.g., dominance or epistasis). As we noted, however, the accumulating evidence on this matter seems to vindicate use of the simple polygenic model limited to additive genetic effects. Related to the missing heritability problem, we showed how there is an empirically motivated shift from study designs optimized for the detection of common variants (i.e., GWAS in samples of unrelated individuals) to those for the detection of rare variants (i.e., WGS in extended families). With the return to family studies for the optimal detection of rare variants, the eigensimplification approach (Blangero et al., 2013) reviewed herein will prove useful in the study design stage as well as in subsequent likelihood analysis. Moreover, as we demonstrated in our description of this approach, heritability is a fundamental parameter in the likelihood function and associated ELRTs, and is a canonical determinant of power to detect genetic effects.

Under the Yang–Visscher approach discussed earlier that focuses on the use of unrelated individuals, all the SNPs from a GWAS are used to estimate an empirical GRK, which in turn allows heritability estimation. As we noted, however, Zaitlen and Kraft (2012) showed that this approach has little power to detect modest effect sizes, requiring 5000–10 000 individuals or more. Historically, this method was developed because GWAS advocates and proponents of the importance of common genetic variants wanted to explain the missing heritability problem (cf. the concerns in the introduction sections in Yang et al., 2010, 2011a,b). This method and associated study design, however, does not represent the optimal strategy to replace the twin paradigm that has dominated human behavioral genetics. Given the statistical inefficiency for both heritability estimation and the detection of rare sequence variant effects that is so important for causal gene identification, we contend that continuing the expansion of heritability studies of human phenotypes under this approach of focusing on unrelated individuals would not be a wise use of resources.

Abstract

'Family and household demography' differs from traditional demography in that it explicitly recognizes and studies *relationships between individuals*. Formal demography focuses on the definition and measurement of families and households, and modeling of types, number, and composition of families and households in the past, current, and future. The entry briefly covers issues in definition, measurement, and modeling. The evolution of modeling from headship rate models to agent-based models is discussed.

'Family and household demography' differs from traditional demography in that it explicitly recognizes and studies *relationships between individuals*. It studies how the core processes of birth, death, marriage, divorce, and migration occur to multiple persons interacting with each other. In doing so, additional relevant processes like entering or leaving coresidence are also studied. In short, relationships between individuals are the central focus of family and household demography. This article outlines the main subfields within the broad area of family and household demography: demography of kinship, households, families, and marriage, respectively. It briefly discusses data issues and definitional problems with a direct bearing on family and household demography. The main part of the article is concerned with formal modeling of households and families, in particular with strategies to overcome the inherent complexity of these models. Three classes of strategies are discussed in more detail: severing the link between related individuals; macro- versus micromodels; static versus dynamic models.

'Family and household demography' differs from traditional demography in that it explicitly recognizes and studies *relationships between individuals*. In traditional demography, the core processes of birth, death, marriage, divorce, and migration are typically studied as occurring to individuals in isolation. In contrast, family and household demography studies how these processes occur to multiple persons interacting with each other. In doing so, additional relevant processes like entering or leaving coresidence are also studied. In short, relationships between individuals are the central focus of family and household demography. This article outlines the main subfields within the broad area of family and household demography, as well as the most important formal concepts.

Classification by Subject Matter

Three types of relationships between individuals can be distinguished (Ryder, 1987):

1. *Consanguineal* relationships run via the fundamental parent–child relation. Any two persons sharing a common ancestor, i.e., linked by a sequence of birth events, are said to be related by blood.
2. *Coresidence* relationships are between persons living together. A foolproof definition of coresidence does not exist (think, for instance, of student housing, lodgers, or part-time households), but 'sharing roof and manger' is not bad for a start.
3. *Conjugal* relationships are between individuals who are married to each other. In fact, living together in marriage is a special form of coresidence. To many people, the bond of marriage is so special that it is (almost or fully) put on the same footing as the consanguineal bonds mentioned under (1). In modern societies, the traditional marriage is gradually replaced by cohabitation (consensual unions). In these societies, 'being married' is more and more replaced by the more neutral 'living together as a couple,' which includes both formal marriages and consensual unions, and frequently also includes homosexual cohabitation. In the first edition of the recommendations for population and housing censuses (Revision 1), the United Nations Statistical Division recommended that "Couples living in consensual unions should be regarded as married couples" (United Nations, 1998, p. 67). In the second revision published in 2008, the recommendation changed. A distinction is made between marital status and *de facto* union status. Marital status is the personal status of each individual in relation to the marriage laws or customs of the country. *De facto* union status refers to extralegal unions (including some consensual unions) of varying degrees of stability common in some countries. The recommendation is: "Couples living in consensual unions may, where appropriate, be regarded as constituting a family nucleus" (United Nations, 2008, p. 131).

The broad field of family and household demography studies all these links between individuals, in their own right but also in relation to other demographic processes (e.g., migration of household, mortality patterns in kin groups). Within the broad field, several subfields can be identified, according to the type of relationship on which they concentrate:

1. *Demography of kinship* studies links of types (1) and (3).
2. *Demography of households* studies links of type (2), but also of type (3) since 'living together as a couple' is a special form of 'living together'.

[†] Original author deceased.

3. *Demography of the family* studies the simultaneous links of types (1) and (3), on the one hand, and of type (2), on the other: a family is a group of coresident kin.
4. *Demography of marriage* studies links of type (3).

Data Issues

The data sources for household and family demography are the same as for demography in general: censuses, population registers, surveys (in kinship studies, genealogies are also sometimes used). However, *definitional problems* are particularly strong in household and family data.

There are two sets of definitional problems. The first relates to criteria for establishing *whether or not a certain relationship exists* between two persons. Examples of such problems include:

1. Two persons (e.g., a mother and a student child) live together during weekends only. Do they belong to the same household?
2. Two persons form a household. How to judge whether they 'live together as a couple?'
3. Two students live in an apartment, occupying separate rooms but sharing kitchen and bathroom. Do they count as one or as two households?

The second group of definitional problems relates to criteria for *classifying households and/or family into categories*, like those used in published household statistics. Examples include:

1. A woman lives with her 30-year-old son. Should this household be termed a lone-parent household?
2. A lone mother cohabits with a new partner. Is this a 'couple with children' household, or rather a 'one-parent family plus other(s)?'

Such definitional degrees of freedom result in actual definitional differences, the consequences of which are potentially very large (Keilman, 1995). Therefore, demographers must be well aware of the precise definitions underlying their household and family data. In descriptive studies, definitional differences can seriously distort international or intertemporal comparisons. In modeling exercises, it is crucial that model parameters are derived from data that are definitionally consistent with the variables in the model. In order to stimulate international comparability of household and family data, the United Nations has specified detailed, extremely useful recommendations for data collection, definition, and tabulation in population and household censuses (United Nations, 2008).

Unit of Analysis

A major problem in the formal demography of families and households is whether the group or the individual should be taken as the primary unit of analysis. Almost by definition, the behaviors of the individuals within the group are highly interdependent. Therefore, analyzing the behavior of the group cannot be done without proper account of the characteristics of its members; conversely, analyzing the behavior of the individual cannot be done without proper account of the characteristics of the group (including those of the other individuals in the group).

Today, most family and household demographers agree that it is most convenient to work at the level of *individuals*. The main reason for this is that, unlike individuals, groups do not have a clearly defined origin and destination in time since members can enter and leave all the time. Thus, modern practice is to define a group in terms of its members and the relationships between them, rather than defining individuals in terms of the group to which they belong.

Because of strong interdependence of within-group behavior, proper modeling of individual family or household members' behavior requires sufficient information on the characteristics of the other individuals involved. In microlevel data, this implies the inclusion of *pointers* to other individuals in the data set, with sufficient detail on the type of the relationship to that other individual. Usually, a reference person is selected, e.g., the oldest person in the household or the head of the household. A main advantage of such data is that it can provide very rich descriptive information on different family and household types, as opposed to standard census breakdowns by just a few main categories. Because of the problems associated with the selection of a reference person in the household to whom all other household members report or designate their relationship, a new method has been proposed for mapping household structures. It is the household relationship matrix method (Maté and Miller, 2003). The household relationship matrix allows for the collection of all relationships between all household members. The method was developed by the census offices in the United Kingdom in preparation of the 2000 census. The Conference of European Statisticians recommended the method for the 2010 Censuses of Population and Housing (United Nations Economic Commission for Europe, 2006).

Naturally, when using sample survey data, proper account should be given to the representativeness of the data at different units of analysis. For example, a random sample of individuals is *not* representative at the household level, since large households will be overrepresented. Weighting schemes must be used to correct this and other potential distortions.

Models in Family and Household Demography

A model is a simplified, quantitative description of reality. In family and household demography, models provide a formal description of the quantitative relationships between family or household characteristics and their demographic determinants and consequences.

At the heart of any modeling exercise lies the specification of the *state space*: the representation of the components of the system of interest. At the level of the *individual*, the state space consists of a number of characteristics or attributes (e.g., age, sex, position in the household, age of spouse, number of children), each of which can take a certain value. At the population level, the state space consists of all possible combinations of attribute values: it is a breakdown of all individuals comprising the population by relevant characteristics.

The ultimate purpose of model building is to obtain an understanding about this multidimensional breakdown of

the total population. A classical demographer is satisfied with a breakdown by age and sex. A marriage demographer would want to add at least 'marital status' as an additional variable. A kinship demographer would want to add a complete breakdown by number of living children, grandchildren, siblings, parents, and so on. A household demographer would want to have, next to age and sex, variables like household size and household type, in a classification that is sufficiently detailed for the research or policy problem at hand. All these demographers have in common that they want to understand why an observed population breakdown is how it is; how particular changes in behavior (for example, total fertility level) would change this breakdown; or how the currently observed breakdown will develop over time (forecasting).

The particular problem in household and family models is that the relevant state space is potentially very large and complicated. This has forced family and household demographers to sacrifice all kinds of descriptive, behavioral, and/or conceptual detail. Evidently, the result is that existing household and family models reflect a wide range of different modeling strategies. Four important classes of these strategies are discussed in the sections below.

Severing the Link

As said before, family and household demography is all about relationships between individuals. A particularly important type of 'sacrifice' frequently made by family and household demographers is to discard most of the information on the characteristics of the individuals *with whom* a particular relationship exists. For example, in the case of a marriage model, a woman aged 40 and married to a man aged 42 is classified as being a married woman aged 40: the information about the age of the husband is discarded.

An example of this 'severing the link' strategy is provided by marital-status models of the multistate type (*see* Multistate Transition Models in Demography). Here, individuals are classified by sex s (m for men, f for women), age x, and marital status i, where i can take the following values: N for never married, M for married, D for divorced, W for widowed. The development over time of the population is described in terms of *events*, which are changes in the attributes of the individual members of the population. For example, next year's 31-year-old married female population is given by (ignoring migration)

$$\begin{aligned} P(f,31,M,t+1) = {} & P(f,30,M,t) + E(f,30,N,M,t) \\ & + E(f,30,D,M,t) + E(f,30,W,M,t) \\ & - E(f,30,M,D,t) - E(f,30,M,W,t) \\ & - E(f,30,M,\text{dead},t) \end{aligned}$$

where $P(s, x, i, t)$ denotes the population at the start of year t of sex s, age x, in marital status i, and $E(s, x, i, j, t)$ denotes the number of individuals of sex s and age x who during year t experience an event from position i to position j. The various numbers of events depend on the size of the relevant population at risk of experiencing the event, and on the rate at which individuals in the population at risk experience the event. For example, the number of women who marry for the first time at age 30 in year t, i.e., $E(f, 30, N, M, t)$, equals the product of two factors: the number of never-married 30-year-old women $P(f, 30, N, t)$, and the first-marriage rate for 30-year-old women $M(f, 30, N, M, t)$.

Given a full set of age-, sex-, origin-, and destination-specific rates, the population by age, sex, and marital status can be projected forward in age and time. Also, a marital-status life table can be calculated. However, a usual characteristic of this model is that marital-status events for one sex are independent of the demographic situation for the other sex. As a result, in this model it is not guaranteed that the resulting population flows for men and women will be mutually consistent. For example, the number of married men having a divorce should equal the number of married women having a divorce, but there is no mechanism in the model to ensure this equality. This problem is known as the *two-sex problem* in nuptiality models (Keilman, 1985a). It is a direct consequence of the fact that the explicit link between marriage partners is missing. There are several solutions to the two-sex problem, each of which introduces fresh problems:

1. To restore the link between marriage partners. This greatly expands the state space, since married persons must be simultaneously classified by own age *and* by the age of their spouse. It also greatly complicates the modeling of numbers of events, since rates must be defined for all combinations of male *and* female ages and marital statuses (*see* Population Dynamics: Two-Sex Demographic Models).
2. A slightly different way of restoring the link between marriage partners is to recast the model in terms of *microsimulation* (see Section Macro- versus Micromodels).
3. To concentrate on one sex (usually: women) only. This is convenient, but obviously unrealistic.
4. To introduce an adjustment mechanism, by which aggregate numbers of events (i.e., aggregated over all ages) are forced to satisfy certain requirements. For example, if the model initially produces 1000 male divorces and 800 female divorces, male divorces are adjusted downward and female divorces upward to result in, say, 900 divorces for each sex. Such procedures are called *consistency algorithms* (Keilman, 1985b; Van Imhoff, 1992). Although such algorithms can be given a satisfactory behavioral interpretation, they nevertheless have an artificial ring and are certainly rough approximations only.
5. A combination of the previous two 'solutions' leads to consistency algorithms that are one-sex dominant. For example, in a female-dominant marital-status model, the total number of male divorces is determined by the female married population and female divorce rates.

Marital-status models are by no means the only models in which 'severing the link' leads to consistency problems. All household and family models which are of the multistate type suffer from essentially the same problem.

Macro- versus Micromodels

In principle, an algebraic representation of a model can be manipulated to study the model's properties. If the model is not too complicated, it could be analyzed in this way. Because family and household models easily get quite complex,

analytic models are rare in family and household demography. A good example of an analytic model (although valid under a number of quite restrictive assumptions only) is the kinship model of Pullum (1987).

For more complex models, analytic manipulation becomes infeasible, so that *numerical simulation* methods have to be used to study the implications of the model. Here, two fundamentally different strategies can be distinguished: *macro*simulation versus *micro*simulation (Van Imhoff and Post, 1998; *see* Microsimulation in Demographic Research).

In macromodels, numbers of events (e.g., 'first marriages to women aged 25') are obtained by applying rates (e.g., 'first-marriage rate for 25-year old women') to a *group* of individuals of a certain size (e.g., 'number of never-married women aged 25'). In micromodels, events are obtained by applying probabilistic decision rules (Monte Carlo experiments) to *individual persons*, separately for a number of individual persons. To follow the example of first marriages: for each individual never-married woman aged 25 in the database, draw a random number between 0 and 1; if this random number is less than the first-marriage probability, the woman is deemed to marry, otherwise she remains unmarried.

In macrosimulation, the population is cross-classified by attributes and calculations are carried out in terms of the cells in the cross-classification: for each cell, the model should evaluate how the number of individuals will change over time. Microsimulation, on the other hand, concentrates on individuals in a population: for each individual, the attribute vector is updated according to the specifications of the model and the results of the Monte Carlo experiments. The storage and retention of information in microsimulation occurs via a *list* of individuals and their attributes; in macrosimulation this is done via the aggregate cross-classification *table*. If there are K attributes and M_i categories for attribute $i = 1 \ldots K$, the table at the macrolevel consists of $M_1 \times M_2 \times \ldots \times M_K$ cells; in contrast, at the microlevel a total population of N individuals can be described by a matrix with $N \times K$ cells. For most applications where a relatively large number of attributes is considered, the size of the aggregate table is much larger than the size of the list. This is particularly the case in household and family models, where characteristics of the individuals to whom relationships exist need to be included. In macromodels this would lead to incredibly large tables.

In micromodels, contrary to macromodels, it is quite easy to keep links between individuals intact, simply by including in the individual records of the database some reference numbers (pointers) to other records (persons) in the database. As a result, the consequences of an event that is simulated for one person can be easily determined and updated for the other persons involved. Thus, the two-sex problem or more generally the consistency problem discussed in the previous section is more or less 'automatically' solved in micromodels. The other side of the coin is that, for events that involve creating a *new* link between individuals, a matching problem has to be solved (e.g., if a woman is simulated to marry, a concrete husband must be identified).

Another main advantage of microsimulation is that it can provide very *rich output*. The output of a microsimulation model consists of a database with individual data that can be aggregated in an almost infinite number of ways. Compare this with the situation in macromodels, where the aggregation scheme is fixed once the model (i.e., the state space) has been specified. Apart from detailed cross-sectional counts, the microsimulation database can also be used to construct longitudinal information, e.g., in the form of individual biographies.

In short, microsimulation offers three main advantages that are of particular relevance in family and household demography: it can handle a large state space; relationships between individuals can easily and explicitly be retained; and it provides richer output.

The best-known microsimulation model in the field of family and kinship is SOCSIM (SOCiodemographic micro-SIMulation), developed by Hammel and Wachter at Berkeley with Laslett at Cambridge University (Wachter et al., 1978; Hammel et al., 1990). The SOCSIM model uses microsimulation to build up kinship links for an initial population of unrelated individuals that is subject to rates of fertility, mortality, and nuptiality (including divorce). Partners are found by a scoring algorithm that has a preferred spousal age difference of about 2 years and restrictions on the age difference of partners. Murphy (2004) used SOCSIM to model the population of England and Wales during two periods of 600 years: 1250 to 1850, and 1750 to 2350. Murphy uses historical rates and contemporary rates to produce the demographic events. Hammel (2005) applied SOCSIM to study the effects of demographic shocks in anthropological populations. A model that is closely related to SOCSIM is CAMSIM (CAMbridge SIMulation), developed for the simulation of kin counts (Smith, 1987). A kin count is a set of numbers expressing how many kin of various types exist for an individual at some time. Zhao (2006) compares the SOCSIM and CAMSIM models.

Dynamic versus Static Models

Populations change over time, and so do household and family structures. Thus, if a model is to describe this change, it must always contain the *time* element in one way or another. In this sense, all demographic models are dynamic by definition. However, there are many ways in which time can be included into a model. Merely adding an index t to all model variables and parameters hardly warrants the term 'dynamic.' A truly dynamic model should not only specify what the system looks like 10 years from now, but also how the system is supposed to get from here to there. In other words, the *processes* that underlie the changes in the system variables should be explicitly included in the model. In a truly dynamic model, the focus is on the *events* of formation and dissolution of relationships between individuals. The LIPRO (LIfestyle PROjections) household model (Van Imhoff and Keilman, 1991; Van Imhoff, 1995; Van Imhoff, 2005) and the ProFamy model (Zeng et al., 1997, 2014) belong to that category. For a comparison of these two models, see Willekens (2009).

In contrast, *static* models do little more than compare household and family structures at different points in time, thus essentially treating the underlying processes of household and family formation and dissolution as a black box. The classical headship ratio models belong to this category. The headship ratio is the proportion of household heads in a population category, e.g., '80 percent of all 40-year old males are

head of a household.' If from a population forecast (*see* Population Forecasts) we know that the number of 40-year-old males will increase from 1000 to 1500, and we extrapolate that the headship ratio for 40-year-old males will increase from 80% to 90%, then it follows that the number of households headed by a 40-year-old male will increase from 800 to 1350. With headship ratios for all ages and both sexes, a full population forecast can in this way be easily converted into a forecast of the number of (private) households. Several generalizations of the classical headship ratio model exist (Kono, 1987; Wilson, 2013). However, they all suffer from the disadvantage that the headship ratio is a static concept: the model cannot tell us why the current ratio of 80% will increase to 90%. The major limitation is that these models do not consider the processes of household formation and dissolution. In a way, the dynamic vs. static issue is gradual rather than fundamental. For instance, if a demographic forecaster hypothesizes that marriage rates will fall by 10% between now and 10 years into the future, one could argue that the marriage component of the model is static since the demographic forecaster does not specify *how* the marriage rates are going to fall. Similarly, the headship ratio method is generally termed static since the changes in age-specific headship are not explicitly specified; however, the changes in the age-specific population size to which these headship ratios are applied *are* explicitly modeled, so the headship ratio model is dynamic at least to some extent.

In fact, leaving some model variables static rather than 'truly' dynamic is an effective strategy to reduce the complexity of the model. The decision of where to stop making variables dynamic is governed by the fundamental tradeoff between information intensity on the one hand, and the capacity to make meaningful predictions on the other. This tradeoff must be faced in every effort of modeling human behavior.

Agent-Based Models

The solutions to the two-sex problem, listed in Section Severing the Link, are all second-best solutions. The two-sex problem typically arises when sex-specific marriage rates are used while interactions between the sexes in the marriage market are disregarded. The two-sex problem can be resolved by explicitly modeling interactions and their changes over time. The theoretical basis is the theory of partner search. During specific stages of life, individuals search for a partner and when a partner meets an individual's preferences, the (one-sided) search is successful. To result in a match, the two partners should have a successful search, i.e., the success should be mutual. A match may result in a stable relationship, cohabitation, and marriage. Becker (1981) shows that in a perfect marriage market the total gain over all marriages is maximized when individuals marry other individuals with similar traits, "regardless of whether the trait is financial, biological, or psychological" (Becker, 1981, p. 71). The process by which likes match with likes is known as *assortative mating*. Partner search is a matching process and assortative mating is one possible outcome of that process. Explicit modeling of the partner search mechanism involves the assignment of behavioral rules and decision rules to individuals and to model the interactions and relationships. This type of model is known as individual-based or agent-based models (ABM). Todd et al. (2005) present such an agent-based model of partner search. Billari et al. (2007) model the behavior of marriageable persons in a social network (the 'Wedding Ring'). The social pressure they experience to marry depends on the proportion married and their duration of marriage.

The formal demography of families and households is a relatively young subdiscipline of demography. It has a history of about 30 years. The subdiscipline faces many challenges (Willekens, 2009). A first challenge is to improve data availability and data quality. Longitudinal data are ideal because they track individuals over time and allow estimating rates of transition that depend on personal attributes. A second challenge is to introduce behavioral theory in family and household models and to discover the individual heuristics that produce the patterns of change in families and households. ABM is the way to go. The nature and structure of families and households vary between cultures and change over time. What is universal, however, is that relationships and ties between individuals result in relatively stable social units the demography of which is highly relevant to society. The demography of these groups is the subject of family and household demography.

Families as Educational Settings

Abstract

Sociocultural theory, social cognitive theory, and bioecological systems theory depict how children's learning occurs within the family. Physical characteristics of the home and parent language use provide a backdrop for children's education. Parents' beliefs that shape their educationally relevant behaviors include perceptions of the child's competencies, expectations, stereotypes, causal attributions, and values. Children learn from direct instruction and by observing behaviors modeled by their parents and siblings. Learning is also shaped by parents' school involvement and selection of children's out-of-home activities. Current scholarship explores cultural, national, and social class diversity in these processes using complex models and sophisticated data analytic strategies.

Introduction

As the primary context for child development, families – including the home environment; parents' beliefs, values, goals, and expectations for their children; parent-child and child-sibling interactions – are an important setting for children's education. Education is viewed here in broad terms, reflecting not only academic standing in the formal setting of school, but also children's cognitive development, including aspects of cognition such as acquisition of language, problem-solving skills, memory development, and general knowledge. In that vein, family influences on children's educational progress are myriad, as family not only provides the primary context for children's development but also reflects the broader societal and cultural contexts within which the family is embedded.

Classic Theories

The educational functions of the family in shaping children's development can be understood by drawing from three classic theories: Vygotsky's sociocultural theory (Vygotsky, 1978), social learning theory (Bandura, 1997), and Bronfenbrenner's (1979) bioecological systems theory. Each of these is summarized below.

Vygotsky's Sociocultural Theory

Vygotsky described children's knowledge acquisition as 'internalization,' reflecting that knowledge is culturally based, and that children's knowledge and skills are acquired through their experiences with social partners. Children's internalization of shared cultural knowledge occurs through the process of guided participation, by which parents and other social partners impart knowledge to children through direct instruction and by showing children how to perform actions. Given the socially constructed nature of children's cognition, at any given time, a child is capable of performing tasks within a given range, which Vygotsky named the 'zone of proximal development' (ZPD). At the lower end of the zone, the child can perform tasks independently. With assistance from a more knowledgeable social partner, the child can successfully complete a level that is higher within the zone. As the child learns more through guided participation, the zone shifts to reflect the child's greater skill and understanding. In order to tailor instruction to the developmental level of the child, parents and other social partners use scaffolding. Scaffolding refers to adjusting the level of support or instruction according to the cognitive level of the child in order that the child might learn new information. Thus, appropriate scaffolding enables the child to perform at a higher level within the ZPD, and might also result in shifting the child's ZPD upward.

For Vygotsky, development occurs as a result of children mastering the tools (e.g., language, counting systems) that are used and valued within their society. Thus, according to sociocultural theory, learning occurs primarily within social interactions and what is learned depends upon the child's culture. Vygotsky argued that both the content and the process of children's educational progress are inherently social in nature. This perspective is quite different from that of Piaget, who viewed the child as an active, independent problem-solver who acquires knowledge about the world through manipulation and active experimentation.

Bandura and Social Cognitive Theory

The social basis of learning is also stressed within social cognitive theory. In contrast to classical learning theory, which posited that individuals must be reinforced to learn a behavior, Bandura argued that many behaviors are learned through observation. For example, in Bandura's famous Bobo doll experiments, children who viewed an adult model using a blown-up doll as a punching bag were more likely to hit the doll themselves than children who did not see such aggression. Thus, Bandura showed that many behaviors are learned by watching a model perform the behavior, and then by imitating the behavior afterward. However, not all behaviors that are observed are learned by the child. Whether or not an observed behavior is subsequently imitated depends on factors linked to the learner (e.g., whether or not the learner was paying attention), characteristics of the model (e.g., whether or not the model is admired), and the situation (e.g., whether the behavior is rewarded). Because behaviors are more likely to be learned when they are modeled by powerful, highly regarded

models, children are particularly likely to learn behaviors that are modeled by their parents and older siblings.

The likelihood that a behavior is learned is shaped by cognitive processes and moral beliefs. In the Bobo doll experiments, children who viewed an adult model punching the Bobo doll and being subsequently punished were less likely to hit the doll themselves than children who did not see the adult punished. Bandura also showed that morality and cognitive abilities cause children to perform learned behaviors selectively. For example, a child might learn that it is acceptable to use certain colorful expressions with siblings and parents but not in front of grandparents.

Bronfenbrenner and Bioecological Systems Theory

Bronfenbrenner's bioecological systems theory posits that child development occurs as a result of interactions between the genetic/biological characteristics of the child and a complex set of environmental systems that have the child at the center (Bronfenbrenner and Morris, 2006). The microsystem includes the contexts in which the child is found, such as home and school. Given that microsystem events are experienced directly by the child, this system usually has the strongest immediate influence. The mesosystem represents interactions between aspects of the microsystem but in the child's absence. For example, a parent's contact with the child's teacher occurs within the mesosystem. The exosystem comprises contexts that do not include the child, but which influence others with whom the child has contact. A parent's experiences in his or her workplace occur within the exosystem. The macrosystem encompasses the broader culture in which the child resides. Therefore, the macrosystem shapes aspects of the other systems and influences the child directly and indirectly. For example, a girl who lives in a culture that values domestic talents in women might be more likely than her brother to learn from their mother how to cook and clean the house. Finally, the chronosystem represents the dimension of time. Timing shapes children's development and learning at an individual level (e.g., with age, the child might spend more time with siblings and less time with parents) and at a societal level (e.g., children born in the 1990s were more likely to learn to use computers at a young age than children born in the 1970s).

Bioecological systems theory depicts how the family context, in which the child resides, is at the center of these overlapping systems which together form the context for the child's learning and development. Examples of these processes are given in the following summary, which describes three broad aspects of the home: the home environment, parents' beliefs, and parent and sibling behaviors.

Fostering Children's Learning: The Home Environment

As noted within bioecological systems theory, the microsystem or contexts within which children reside are particularly influential in shaping their development (Bronfenbrenner and Morris, 2006). Thus, the day-to-day environment in which the child lives, breathes, and plays shapes learning profoundly. Two aspects of the home environment are discussed here: the physical characteristics of the home environment and parent language use.

Physical Characteristics of the Home Environment

In attempts to understand individual differences in children's academic skills at the point of school entry and as they proceed through primary and secondary school, researchers have noted differences in characteristics of the home environment. Home environments that provide the best opportunities for children to learn are those in which children are safe from environmental toxins and trauma, have access to nutritious food and safe drinking water, are cared for by responsive caregivers, and enjoy residential stability (i.e., neither the individuals who constitute the family unit nor the location where they reside changes frequently) (Duncan et al., 2010). Children who live in neighborhoods with high levels of noise due to an adjacent airport or highway score lower on measures of attention, memory, and reading comprehension than children from quiet neighborhoods. Crowding – having a large number of individuals within a small space – is also associated with lower cognitive skills in children (Evans, 2006).

Children's exposure to television and other technology is recognized as a home characteristic that shapes learning and cognitive development. Although watching educational television programming has some benefits, particularly for children who live in impoverished environments, in general television viewing is associated with poorer child outcomes (Schmidt and Anderson, 2007). In contrast, research shows that use of computers enhances learning and cognitive development, even at early ages (Hofferth, 2010). It is not yet clear to what extent and in what ways availability of technology such as smart phone applications influences children's learning and development.

Children's educational progress is also shaped by the availability of formal and informal learning materials such as books, games, and toys. These materials foster children's development when they are appropriate for the child's age (Bradley et al., 1988). In infancy, children benefit from viewing complex patterns and manipulating objects. After infants learn to crawl, and later to walk, they benefit from adequate space in the home where they may freely explore without danger of injury. Age-appropriate games, books, and activities foster the child's development of verbal, spatial, and problem-solving skills. Researchers have noted that low-income families often do not have as many learning materials available to children in the home as higher-income families (Duncan et al., 2010). These differences in home environments lead to differences in children's skills at the point of school entry – differences that usually remain stable as children proceed through school.

Parent Language

Large differences have been found across families in parents' use of language in the home. The total amount of spoken language, parents' use of different words (i.e., the size of their vocabularies), the length of parents' statements to children, and the frequency with which parents respond to child-initiated conversation are all related to children's intelligence at a later

age (Hart and Risley, 1995). Parents' language use with infants guides the development of the infant's ability to distinguish among phonemes. Children speak at an earlier age if their parents speak directly to them before the infant produces recognizable speech.

Many caregivers spontaneously use 'motherese,' which is speech that is characterized by short utterances with common words, simple syntax, and repetition, usually using a high-pitched voice. Such infant-directed speech provides the scaffolding to help the young child to learn words and concepts. Sensitive caregivers often provide stimulation that fosters verbal learning – for example, by introducing new words and concepts at an appropriate rate so that the child can learn them.

For immigrant children, educational progress is shaped by whether or not English is their first language. On average, Latino children in the United States who speak a language other than English at home begin kindergarten with significantly lower math and verbal skills than their non-Hispanic White peers (Reardon and Galindo, 2009). However, these achievement gaps narrow between kindergarten and Grade 5, reflecting that as children gain proficiency in English, their school achievement catches up to that of peers. Language use in the home also influences the formal educational progress of immigrant children indirectly through parents' school involvement. Research with Latino parents has shown that communication difficulties for parents who do not speak English, combined with cultural misunderstandings (e.g., hesitancy to ask a teacher questions for fear of showing disrespect) lead to less school involvement on the part of Latino parents (Hill and Torres, 2010). However, Latino parents may compensate for less school involvement by providing more monitoring in the home of children's homework completion (Aud et al., 2010).

Parents' Beliefs and Values

Parents' beliefs affect children's educational outcomes both through their influences on parental behaviors and on children's developing beliefs (Okagaki, 2001). For instance, a parent will speak to her 6-month-old daughter more often if she believes the infant can benefit from 'conversations' with an adult partner. Parents' beliefs also shape the developing beliefs of their children, many of which serve a motivational role for the child. Thus, a child whose father conveys that a failure was due to lack of effort rather than lack of ability might be more likely to persevere on a future task (Weiner, 1979). The following types of parental beliefs are described here: parents' expectations for their children and perceptions of children's competence, cultural stereotypes about group differences in skills, causal attributions about the reasons for children's behaviors and their academic outcomes, and parents' values and interests.

Parents' Expectations of the Child and Perceptions of Children's Competencies

Whether or not they have been verbalized, parents have expectations for the behaviors they expect of their children at given ages. Most parents also have expectations for their children's performance in school and eventual educational attainment.

Parents' Expectations for Mature Behavior

Parents vary tremendously in their beliefs about children at different ages (McGillicuddy-De Lisi and Sigel, 1995). Some parents expect that 18-month-olds can be potty-trained, whereas other parents are nonplussed when the 3-year-old continues to have 'accidents.' Some parents may expect their 3-year-olds to master rudimentary concepts of number and quantity that other parents would not expect before the age of seven. Although parents may not be conscious of many of these beliefs, such beliefs nevertheless shape everyday activities in the household, family rules, and the messages children are given – both blatant and subtle – regarding their abilities. For example, parents who believe that an 8-year-old is capable of planning might expect their child to pack his/her school lunch; select weather-appropriate clothes; and budget time to include homework, soccer practice, and leisure in a given evening.

Parental expectations that infants and toddlers are able to self-regulate their behavior (e.g., refrain from crying when they experience distress) have been linked to inappropriately punitive parental behavior and more negative child outcomes (Burchinal et al., 2010). Among older children, expectations for mature behavior that are clearly communicated to the child and that are accompanied by warmth and nonpunitive discipline are associated with better child outcomes (Baumrind, 1973).

Parents' Perceptions of Children's Abilities and Expectations for Educational Attainment

Parents' perceptions of their children's abilities influence the activities they choose for their children and the extent to which they encourage their children in certain pursuits. For example, a parent who views a child as talented athletically might encourage the child's participation in team sports. In this case, parent perceptions of the child's competence influence whether or not the child is encouraged to try out for a soccer team. Parent perceptions also shape the level of challenge that the parent provides for the child in learning situations (Vygotsky, 1978). Parents balance their level of support and challenge based on their view of the child's current competence level.

In terms of parents' expectations for their children's academic success and their eventual academic attainment, it is clear that children's competencies inspire parents' expectations (i.e., parents have higher expectations of more competent children). In general, the research literature also indicates an independent effect of parent expectations on children's achievement: Parents with more ambitious expectations have, on average, children who excel academically (Zhang et al., 2011). Parents who have high educational attainment expectations for their children and who perceive that their children are capable are likely to foster achievement striving in their children and to provide supportive learning environments. Both parents' perceptions of their children and their expectations for their children's future accomplishments are often shaped by cultural stereotypes, which are discussed next.

Cultural Stereotypes

Within any society, cultural stereotypes shape expectations of and behaviors with the child. Cultural stereotypes associated with gender differences are common in the United States and many other countries. For example, girls are assumed to be better attuned to emotions and social relationships than boys, and therefore parents are more likely to talk about feelings with daughters than with sons. Although stereotypes are often based to some extent in actual group characteristics (e.g., many Scandinavians are tall and blonde), stereotypes sometimes lead to biased perceptions of group members, memory distortions, and differential treatment.

Parents' gender stereotypes are particularly powerful in shaping family processes. Because daughters tend to be viewed as more vulnerable than sons, boys are more likely to be encouraged to pursue activities outside the home that promote agency and autonomy. Girls, in contrast, might be encouraged to spend more time with parents, and usually have greater responsibility for domestic tasks such as cooking, cleaning, and care of younger siblings (Crouter et al., 2001). The gendered nature of children's experiences within the family is more pronounced in families where parents hold traditional gender beliefs. Children learn the behaviors modeled by their parents and often adopt these behaviors themselves as they reach adulthood.

Gender stereotypes – as well as other stereotypes based on social groups – vary across cultural groups. Within Latino families, for example, men are traditionally expected to be the economic providers for their family and to be responsible for most important decisions. Women, in contrast, are traditionally expected to be submissive to their husbands, passive, and self-sacrificing for the good of the family. The extent to which these traditional stereotypes are upheld within the family as well as attitudes in the child's mesosystem, exosystem, and macrosystem will influence the degree to which the child internalizes gendered norms and will practice such behaviors as an adult.

Parents' Causal Attributions regarding Their Children's Behaviors

Classic psychological theories (e.g., Rotter, 1966; Weiner, 1979) and empirical research demonstrate that individuals vary in their beliefs about the reasons for behaviors and for performance outcomes, and that such attributions shape both responses to others and expectations about future behaviors and outcomes. Two aspects of parents' attributions are discussed here: Parents' assumptions about the reasons underlying children's behaviors and misbehaviors, and parents' beliefs about the reasons for children's academic successes and failures.

Parents' Attributions about Child Compliance and Misbehaviors

Parents' beliefs about children's behavior shape their discipline practices, how and to what extent autonomy is fostered, and age-related expectations of their children. For example, a parent who believes that an infant is crying because she is willful and angry with her caregivers might be punitive (Burchinal et al., 2010). In contrast, a parent who attributes the crying to fatigue, hunger, or another source of physical distress will be more likely to comfort the infant and eliminate the source of distress. Parents of teenagers might attribute their children's misbehavior to peer pressure, poor judgment exercised on the road to learning autonomy, disrespect, or stupidity. Parents usually choose responses to child misbehaviors that reflect their attributions.

A substantial body of literature indicates more positive cognitive and social outcomes for children whose parents show warmth while exhibiting firm yet flexible control, a style called democratic parenting by Baldwin (1955), and later described by Baumrind (1973) as authoritative parenting. Authoritative parents rely primarily on reasoning as a discipline tool rather than punishment and view their children's good behavior as the primary goal of their parenting rather than obedience. Thus, parents who value their children's autonomy, and whose knowledge and beliefs are consistent with an authoritative parenting style are more likely to foster educational progress in their children, as marked by school grades, low incidence of discipline problems, and healthy self-esteem.

Some recent research indicates cultural variation in the relationship between parenting style and children's outcomes, both in the importance of autonomy encouragement and the possible detrimental effects of harsh discipline. Harsh discipline may be less detrimental to children in cultures in which it is sanctioned and in environments where misbehavior might put the child in danger (Dodge et al., 2005). The extent to which autonomy is valued and encouraged also differs across cultural contexts.

Parents' Attributions about Children's Academic Successes and Failures

For children in a formal educational setting, children and parents form beliefs about the reasons underlying the child's academic outcomes. When the child's academic success is attributed to ability, expectations for future successes are high because ability is viewed as an internal and stable characteristic of the child. In contrast, if success is attributed to an external, uncontrollable cause such as luck or an easy task, then parents and children have less confidence in future successes (Weiner, 1979). Causal attributions influence children's outcomes through their motivational effect on children's persistence in the face of failure and/or challenging tasks as well as through parents' and teachers' behaviors with children. Parents' attributions are related to their behaviors with their children such as homework support and encouragement to take advanced coursework.

Because academic stereotypes by their very nature include attributional content (i.e., one social group is assumed to be more talented than another), researchers have investigated linkages among cultural stereotypes, causal attributions, and outcomes such as parent behaviors with their children. This research has shown that parents have different expectations of the math successes of sons as compared to daughters, and that these expectations are played out in the types of activities that are provided to children in middle childhood (Jacobs et al., 2005).

Parents' Values and Interests

According to expectancy-value theory, goal-directed actions are guided by expectations that certain behaviors are likely to lead

to a desired outcome and by the extent to which the outcome is valued (Fishbein and Ajzen, 2010; Wigfield and Eccles, 2000). Therefore, a child will pursue a task (and parents will encourage children in that pursuit) when they believe the child is capable of mastery and when the task is valued. According to Wigfield and Eccles (2000), a goal is valued if the individual has high interest in the domain, if the goal is viewed as useful and important, and the cost of achieving the goal is not prohibitive.

Parents' values and interests comprise an important mechanism that leads to differences in children's learning both within and across cultures. Whereas knowledge of which basketball teams have made it to the Final Four is an important information to be learned in some families, other families place little value on sports knowledge and instead might have political discussions at the dinner table each evening. Parents' values and interests have the largest impact on children's learning in early childhood. By adolescence, youths' goal pursuits are increasingly shaped by peers and their own interests. However, families continue to be an important source of influence.

Parents' and Siblings' Behaviors

The beliefs and values that were discussed in the prior section influence children's educational outcomes through several mechanisms. Parents' beliefs and values are reflected in the structuring of the home environment – for instance, in parents' selection of toys for the child. Parents' beliefs also shape their behaviors – both direct interaction with the child, and behaviors that the child observes. In this section three aspects of parent behaviors are discussed: parents' and siblings' direct instruction and behaviors as role models for the child, parents' school involvement, and selection of out-of-home activities.

Parents and Siblings as Role Models and Teachers

As depicted in social learning theory, one way in which families have profound influences on children's learning is through the modeling of behaviors. Children who observe their parents reading are more likely to read themselves. Children are more likely to learn about organized sports if parents and/or siblings are involved in such sports. Children become 'socialized,' learning the acceptable behaviors of their culture, by observing parents and siblings. Thus, for example, a young Korean child will learn that a loud belch is an appropriate way to show appreciation for an excellent meal, whereas a child in Kansas will learn that such noises should be suppressed at the table.

Through observing parents and other family members, children learn cognitive skills such as language, social skills such as how to greet a stranger, and cultural attitudes such as appropriate dress for a party. The toddler observes an older sibling's interactions with friends and imitates that behavior later in other social situations. A young adolescent internalizes a social stereotype after observing his parent consistently becomes tense when encountering members of another racial group.

In addition to these examples of observational learning, children learn from the direct instruction of their parents and siblings. From birth onward, parents and siblings are an important source of children's knowledge. Through everyday conversations and activities with family members, children acquire concepts of schemas (e.g., what a visit to the doctor's office entails), grammar, and mathematical concepts (e.g., the early distinction between 'one' and 'more'; how to fairly divide the last piece of cake). Children learn memory strategies (e.g., where can I put my show-and-tell item so I will not forget it tomorrow morning), metacognitive knowledge (I cannot concentrate on my homework while big brother is listening to that music), and problem solving (How should I clean up this spilled sugar?).

Instruction that takes place in the home is markedly different from that found in the school setting, in that it is largely unplanned, informal, and context-grounded, rather than the planned, formal, and context-independent instruction that occurs in school. Most instruction in the home occurs spontaneously based on the specific events, feelings, and needs of a given moment in the family life. Because it is so highly context-dependent, this instruction from siblings and parents provides the basis for most of the child's knowledge and skills of how to survive in the day-to-day world.

Parents' School Involvement

One way in which parents model educationally oriented behavior to their children and shape the child's microsystem and exosystem is through their actions directed toward the child's formal education. Such school involvement takes many forms, occurring both inside and outside the home. In the United States, parents who volunteer in the child's classroom, attend school events, and find other ways to interact with teachers and other school personnel are more likely to be viewed positively by school personnel, have greater knowledge of school rules and events, and are more aware of what their children experience at school. Such school-directed involvement is associated with more positive achievement outcomes for children, perhaps because of parents' improved ability to provide scaffolding for their children, or perhaps because teachers tend to interact more with children whose parents are involved at school.

Other parental school involvement occurs within the home setting, where parents monitor children's homework completion, encourage and support them when children are challenged by difficult academic tasks, and provide tangible supports for children's academic progress. Researchers have noted that parents who are not at ease in the school setting – perhaps because of having little formal education themselves, or perhaps (for immigrant parents) because they are not fluent in the language used at school – are often likely to be involved in children's schooling in these ways within the home.

Low income, racial/ethnic minority, and immigrant parents face many barriers to school-focused involvement in their children's schooling (Nzinga-Johnson et al., 2009). In addition to the language barriers faced by many immigrant parents, educational practices within the host country may be foreign to immigrants (Hill and Torres, 2010). For example, extracurricular activities such as sports, academic clubs, and arts events (theater, music, dance) that are common in most schools in the United States are uncommon in many other countries. Single parents and parents who work more than

one job usually find it more challenging than dual-parent families to attend school events or volunteer in the classroom. Ethnic/racial minority parents who have had prior discriminatory experiences with school personnel may avoid interactions with their child's teacher, or might have interactions that are distrustful or hostile. Whereas such parental school involvement is encouraged and often expected in the United States, in many other countries parental presence in the school setting is not expected and in some cases is viewed negatively.

Out-of-Home Activities

As noted by Bronfenbrenner in bioecological systems theory, the immediate microsystem of the home is only one context in which families provide the backdrop for children's learning. Parent employment, which is usually part of the child's exosystem, shapes the child's development in several ways. Early investigations in parent employment and children's outcomes were mostly group comparisons aimed at determining whether or not maternal employment had a detrimental effect on children. These investigations indicated no differences in quantity or quality of parenting systematically related to maternal employment status. More recent research has identified process variables related to parent employment that have both positive and negative influences on children. According to scarcity or stress theory, parents have a limited amount of time and energy, and parental employment is deleterious to children's developmental outcomes to the extent to which it decreases parents' time, energy, and patience. Stress theory reflects a strong trend in the United States and many other industrialized nations: Namely, in spite of the impressive technological advances of the past century, most parents work harder than ever (Schor, 1991). Particularly as maternal employment rates have increased, the everyday lives of children have become harried. Thus one consequence of parental employment for children is the resulting stress associated with parental employment-related absence, whether that absence is actual or psychological, because stressed parents are preoccupied, tired, and impatient. A second consequence of demographic changes in employment patterns is that children spend a greater amount of time with other caretakers. Therefore, parents' selection of day care for infants and preschoolers, and their choices of afterschool activities for school age children have real impact on children's developmental outcomes.

Parental employment can also benefit children's educational progress. Parents gain in income, self-esteem, competency, and social support through their employment; these benefits for parents may translate into benefits for children. Mothers who are employed in professional positions serve as positive role models for daughters. In addition, parents' work characteristics are related to the quality of their parenting. Parents who enjoy their work, who are socially rewarded for it, and who are intellectually challenged in the work setting are more likely to show warmth and greater flexible but firm control with their children than parents who have less satisfying employment.

Parents of infants and preschoolers decide at what age the child will begin to spend significant amounts of time outside the home, and where that time will be spent. In middle childhood and adolescence, the child's afterschool activities and vacation time might be selected jointly by the child and parents, as well as other family members. Because of the interests, occupations, and habits of parents, siblings, and extended family members, one child may spend free afternoons playing basketball, while another goes to the shopping mall. Such influences demonstrate ways in which the mesosystem (e.g., at a school open house, a teacher suggests to the parent that a child enroll in a summer science camp) and exosystem (e.g., because of the parent's work expertise, the family uses vacation time to attend a national decathlon featuring solar-powered cars) might shape the child's microsystem.

Current Research Directions

In recent decades, researchers have made a concerted effort to expand our understanding of children's educational progress to cross national, racial, cultural, and social class lines. Whereas the majority of research studies in the twentieth century were conducted with White, middle class Americans, scholars are attempting to understand ways in which children's development varies in other countries and cultures, and the extent to which cultural context shapes such processes. In the United States and elsewhere, immigration patterns are changing the characteristics of the population, and therefore scholars are interested not only in how children's development differs across cultural groups, but also how the acculturation process shapes children's experiences. Thus, for instance, a child whose parents are not fluent in the language of the host country might have responsibilities for communication between his parents and school officials.

Another change in scholarship is a move toward more complex models in understanding child learning and development. The development of more sophisticated data analytic procedures has permitted researchers to address questions such as how change over time differs within and across groups, and how such change is differentially influenced by multiple levels of children's contexts. For example, current data analytic techniques permit researchers to determine how race composition of the child's classroom – which changes from year to year – is related to change in the child's academic performance, how this change differs according to the race of the child's teacher, and how these effects differ across schools and across racial groups within schools. Whereas 50 years ago researchers were more likely to focus on a single context or relationship (e.g., parent–child interaction during problem solving), researchers are increasingly examining how development emerges from the interplay of numerous agents (e.g., parent, sibling, and peer influences operating together) and at multiple levels (biological, behavioral, and societal).

The greater complexity in research designs is a reflection of changes in the theoretical approaches to understanding development, in which behavioral processes are viewed as emerging from the interplay of various systems ranging from the genetic to the cultural. Developmental researchers recognize that developmental processes such as children's educational progress can be understood best when taking into account these

multiple levels, and that interactions across the levels occur across time and lead to new patterns of organization in context (Spencer et al., 2009).

Abstract

This article discusses the emergence and development of the historical study of the family and interprets them in the larger context of social history. It addresses the following issues: the emergence of the field of family history; household structure; developmental perspectives; kinship; the family's interaction with the process of industrialization; family strategies; and future directions in the field of family history.

This article examines the emergence of the history of the family as an interdisciplinary field in Europe and in the United States. It traces the field to its origins in France and England and its subsequent development in other European countries, Japan, and the United States. It discusses the characteristics of the field due to its origins from both historical demography and social and cultural history, particularly from the 'new' social history. The article examines the various dimensions of the historical study of the family, starting with the discovery of the continuity of a nuclear household structure since preindustrial society, and the presence of 'modern' characteristics of demographic behavior (such as family limitations) in Western Europe and North America, prior to industrialization. It proceeds to explore subsequent discoveries of the importance of kinship networks outside the household, and the salient role of kin in the process of industrialization and in adaptation to industrial life. Examining the development of scholarship in the History of the Family in the 1980s and 1990s, the article traces the emergence of the life-course approach, in response to the need for a developmental perspective and its utility in examining the interaction of 'individual time,' 'family time,' and 'historical time.' The article further examines the family's interaction with the process of industrialization. Contrary to prevailing myths about social breakdown, it emphasizes the family's role as an active agent in that process. In doing so, it discusses both the earlier stages of 'protoindustrialization' and the emergence of the factory system. In assessing the family's role as an active agent, it explores family strategies as an important process of family decision-making. Finally, the article examines critically, earlier studies of 'grand' changes in the family over time and the meaning of 'modern' family patterns. The article concludes with suggestions for continued and future research.

Emergence of the Field

Recent historical research on the family has revised some widely held myths about family life in the past, as well as generalizations about the impact of the grand processes of social change on the family and society. Family history has complex roots in both the historical demography of the early 1960s and the 'new social history' of the same period. Particularly in the United States, it has shared with the latter a commitment to reconstructing the family patterns of ordinary people and viewing them as actors in the process of change. Contemporary historians of the family have sought to reintroduce human experience into historical research and to emphasize the complexity of historical change (see Hareven, 1971, 2000a; Tilly, 1987). Hence, research in the history of the family explores previously neglected dimensions of human experience such as growing up, courting, getting married, bearing and rearing children, living in families, becoming old and dying. The formidable goal has been to understand the family in various contexts of change and at different points in historical time. In short, the historical study of the family represents an effort to understand the interrelationship between 'individual time,' 'family time,' and 'historical time' (Elder, 1978).

Before systematic historical research on the family began, various social science disciplines had generated their own myths and grand theories about continuities and changes in family behavior in the past. Sociologists in particular argued that, in preindustrial societies in the west, the dominant household form had contained an extended family, often involving three coresident generations, and that the 'modern' family – characterized by a nuclear household structure, family limitation, the spacing of children, and population mobility – was brought about by industrialization. Associated with these generalizations was also the popular myth that industrialization broke up traditional family patterns and community life. By providing a perspective on change over time, as well as on family behavior within specific social and cultural contexts in discrete time periods, historical research on the family has led to the rejection of these assumptions and to the resulting questioning of the role of industrialization as a major watershed in this field for American and European history (Wrigley, 1972; Goode, 1963).

Over the three-and-a-half decades of its existence, family history has moved from a limited view of the family as a static unit at one point in time to an examination of the family as a process over the life course of its members; from a study of discrete domestic structures to the investigation of the nuclear family's relations with the wider kinship group; and from a study of the family as a separate domestic unit to an examination of its interaction with the worlds of religion, work, education, correctional and welfare institutions, and with processes such as migration, industrialization, and urbanization (Vinovskis, 1977; Hareven, 1982).

As research in this field developed, new findings and approaches have led to the revision and augmentation of the pioneers' approaches. Efforts to explore decision-making processes within the family have led to an investigation of strategies and choices that individuals and family groups make. The life-course approach has added an important developmental dimension by focusing on age and cohort comparisons in ways that link individual and family development to historical events. Research also expanded chronologically to cover antiquity, and geographically to encompass southern Europe, eastern Europe, the Mediterranean, Japan, China, and Latin America, in addition to Western Europe, North America, and Japan. The cumulative impact of studies in the history of the family has been to revise simplistic views of both social change and family behavior (Reher, 1997; Andorka, 1994; Plakans and Wetherell, 1999; Todorova, 1997; Halpern et al., 1996; Hayami and Uchida, 1972; Kurosu, 1996; Lee and Campbell, 1997; Lee and Feng, 1999; Borges, 1992; Kuznesof, 1997).

The emergence of the history of the family as a special area of inquiry received its major impetus from the publication of Philippe Aries's *Centuries of Childhood* (1960 in French and 1962 in an English translation). Aries argued that childhood as we know it originated only in the early modern period and that its discovery was closely linked to the emergence of the 'modern' or conjugal family, in which parents' private relationships with their children were more important "than the honor of a line, the integrity of an inheritance, or the age and permanence of a name" (Aries, 1962: p. 393). By linking the 'discovery' of childhood to transformations in family and social structures as well as economic and demographic changes, Aries inspired a whole generation of scholars.

Along another line of research, historical demographers in France in the early 1960s provided family historians with a powerful 'new weapon' for the analysis of demographic processes. Louis Henry and Pierre Goubert had developed a family reconstitution technique in the 1950s. Using genealogies, and marriage, baptismal, and death records from parish registers, this method enabled demographers to reconstruct aggregate patterns of fertility, nuptiality, and mortality for vast numbers of people and, in some instances, over several generations (Henry, 1953).

From the 1960s on, historical demography and family history in France developed into two parallel but interrelated streams. One continued to concentrate on demographic analysis, along the lines of Henry and Goubert; the other, influenced by Aries, anthropology, and the French social history tradition, integrated demographic analyses with patterns of family and sexuality, linking community and social and cultural variables with *mentalité*, as exemplified in the work of Emmanuel LeRoy Ladurie (1978), André Burguière (1987), Jean-Louis Flandrin (1976), and Martine Segalen (1991), among others. Family reconstitution subsequently became a powerful tool in the hands of the Cambridge Group for the History of Population and Social Structure.

Established in 1964, the Cambridge Group adapted the family reconstitution method to English parish registers, while also pursuing analysis of seventeenth-century nominal household registers. Wrigley found in the decline in fertility in the seventeenth century and in its recovery in the eighteenth century, evidence that rural births and marriages responded to changing economic conditions. He concluded that the demographic transition involved a change "from a system of control through social institution and custom to one in which the private choice of individual couples played a major part in governing the fertility rate" (Laslett, 1977; Wrigley and Schofield, 1981).

Such demographic analyses for France and England, and subsequently Sweden, Austria, Germany, and The Netherlands, revealed that, in the preindustrial period, people married later than had been generally assumed, couples practiced some form of family limitation and child spacing as early as the seventeenth century, households were predominantly nuclear rather than extended, and preindustrial populations experienced extensive geographic mobility (Laslett, 1965; Goubert, 1977). Late marriage served as a method of family limitation. It was also closely related to the expectation that a newly wed couple would establish a separate household and be self-supporting, while continuing to contribute to their families of origin. Linking late age at marriage to the nuclearity of the household, John Hajnal (1965) developed his model of the 'West European Marriage Pattern,' which served as the basic model for the analysis of West European families until it came under criticism. Hajnal claimed that marriage patterns in historic Europe could be differentiated with a line drawn approximately from St. Petersburg on the Baltic Sea to the Adriatic Sea. West of this line marriages tended to be relatively late (late 20s) for both genders, and substantial portions of the population did not marry at all. East of this line, marriage for both genders was relatively early (late teens) and marriage was nearly universal. He identified the 'western' pattern as the 'European' pattern and suggested that the 'eastern' pattern was shared by many developing countries (in the 1960s).

Household Structure

Using nominal census records, Laslett found evidence of continuity in nuclear household structure in England, at least since the sixteenth century. A landmark volume published by Laslett and Wall (1972), containing articles on household structure for various countries, including Japan, concluded that preindustrial households in Western Europe and North America affirmed these findings and dispelled the previously held assumption that industrialization brought about a nuclear family form. Although Laslett's early work emphasized the persistence of a nuclear 'family,' the major unit discussed was the household, not the family. A household is not identical with a family, as the domestic group may include nonrelatives as well. Nor is a 'family' restricted to the household, as extended family ties transcended the household unit (Goody, 1972; Hareven, 1982).

Subsequent studies showed that coresidence with extended kin tended to increase, not decrease, after the 'industrial revolution,' because of the need of newly arrived migrants to industrial cities to share housing space (Laslett and Wall, 1972; Hayami and Uchida, 1972; Anderson, 1971). David Herlihy (1987) and Richard Smith (1979), respectively, traced a nuclear household structure in medieval Tuscany back to the twelfth century, as well as in England; and, in the medieval

village of Montaillou, LeRoy Ladurie (1978) found a variety of forms of family structures in the *domus* (household), ranging from ordinary nuclear families to various complex configurations. Household structure varied over the life course of its members, in relation to the economy and migration.

Such early discoveries also led to the formation of new generations and stereotypes: by combining the findings about the nuclearity of the household with the Hajnal thesis on the Western marriage pattern, Laslett developed a typology of the 'western family,' which he characterized as having a simple nuclear household; a relatively late child-bearing age; a relatively narrow age gap between husband and wife, with a relatively high proportion of wives older than their husbands; and the presence in the household of 'life cycle' servants unrelated to the family with whom they were residing. By contrast, he characterized the South European and Mediterranean family type as having complex household structures and early marriage, in which nuclear households are formed by the breakup of extended ones, rather than through marriage (Laslett, 1977). These typologies, along with the Hajnal thesis, later came under criticism. David Kertzer refuted the thesis that links early female marriage to joint household organization as a characteristic of the 'South European' family pattern. He showed variability in household structures in Italy, depending on types of landholding and sharecropping. Similarly, Haim Gerber, on the basis of his analysis of urban Turkish households in the seventeenth century, questioned stereotypes of the traditional 'Middle Eastern family' (Kertzer and Hogan, 1989; Gerber, 1989).

In New England, when interpreted in the context of economic and social institutions (such as landholding, inheritance, community structure, and religion), demographic patterns served as the backbone of complex family and community analyses. In his analysis of household and family structure in colonial Andover, Massachusetts, Philip Greven revealed the power relations between fathers and sons and the limits of the sons' autonomy based on inheritance. He found that households were primarily restricted to members of the nuclear family and nonrelatives, but a 'complex web' of family connections reinforced by proximity of residence, often on the same land, permeated the community (Greven, 1970). Demos, in his study of colonial Plymouth, Massachusetts, used family reconstitution, the analysis of nominal census records and a great variety of other sources to reconstruct family and community patterns (1970). He also found a predominance of nuclear households, but these differed considerably from contemporary ones. Families were larger then and included nonrelatives, such as servants, apprentices, and boarders and lodgers in the households. Age configurations were also different; in some families, the oldest child in the household would be an adult while the youngest was still at the breast.

A major critique of early studies of household structure was their reliance on 'snapshots' in the household schedules listed in the census at one point in time. On the basis of his reconstruction of peasant households in the villages of Heidenreichstein in northern Austria in 1763, Berkner (1972) provided evidence that household structure changed several times over the course of the family's life, as it moved through its cycle – from a stem family to a nuclear one, and later to a stem family again, in relation to inheritance. Households were not static. At the same time, Demos' reconstruction of the stages of the life cycle in Plymouth demonstrated dynamic movements of individuals within and across families and households, in relation to the religious and cultural prescriptions of Puritan society (Demos, 1970).

The presence of 'life cycle' servants – young men and women in their teens who lived and served in other people's households in the transitional period between leaving home and marrying – which Laslett found in English villages, as well as the presence of other unrelated individuals in the household, proves the remarkable flexibility of households in the past. Nuclear households included nonrelatives such as servants, apprentices, boarders and lodgers. Similarly, in nineteenth-century American urban households, Modell and Hareven (1973) found a high proportion of boarders and lodgers, who provided important substitutes for children who had left home. Households expanded and contracted over the life course and in accordance with the family's needs.

Developmental Perspectives: The Life Course

The discovery of boarders and lodgers in nineteenth-century households and of the overall fluidity of household structure led historians of the family to search for a framework that would allow them to capture the movement of individuals through various household forms over their lives and the changes in the composition of the family and the household under various historical conditions. The family cycle model, which was used originally to identify changes in family structure, became unsatisfactory, because the stages of the family cycle were derived from contemporary American middle-class families, and were a priori. As Glen Elder explained, the family cycle identifies stages of parenthood rather than the more dynamic aspects of individual transitions into and out of various family roles (Elder, 1978).

Dissatisfaction with the family cycle model led historians and sociologists to develop the life-course approach, which has introduced a dynamic dimension into the historical study of the family, and has moved analysis from a simplistic examination of stages of the family cycle to individuals' and families' timing of life transitions in relation to historical time (Hareven, 1978; Elder, 1978). According to the life-course paradigm, the pace and definition of the timing of life transitions, such as starting work, leaving home, and getting married, are determined by their social and cultural context. On the familial level, timing involves the synchronization of individual life transitions with collective family ones (Elder, 1978). For example, using both demographic evidence and prescriptive literature, Modell, Funstenberg, and Herschberg found a major historical change in American society over the past century, from the 'erratic' timing of life transitions governed by collective family needs to more individualized timing in conformity with age norms (Modell et al., 1976).

Life-course research also illuminates the links between behavior and perception. While the actual timing of life transitions can be reconstructed from demographic records, its meaning to the individual and family members undergoing these transitions hinges on the examination of qualitative, subjective sources (Neugarten and Hagestadt, 1976;

Bourdelais, 1993; Hareven and Masaoka, 1988; Hareven, 2000b). A life-course perspective has also made an important contribution to the study of kinship by directing attention to the changing configurations of kin with whom individuals 'travel' together over their lives. Such configurations are formed and reformed; they change in their composition, in their relationship to the individual and the nuclear family, and in relation to each other over the life course.

Kinship

During the second decade of the development in the field of family history, kinship ties outside the household received increasing attention. Rather than being isolated, nuclear households were embedded in extended kinship ties outside their confines. Members of the nuclear family were engaged in various forms of mutual assistance, collaboration, and rituals with extended kin. Even though aging parents did not generally reside in the same household with their married adult children, they lived in the vicinity, often on the same land (Greven, 1970; Berkner, 1972; Smith, 1979; Sabean, 1998).

For nineteenth-and twentieth-century urban populations, Anderson (1971) and Hareven (1982), respectively, have documented the central role of family members and more distant kin in organizing migration from rural areas to industrial cities, in facilitating settlement in urban communities, and in helping migrants adapt to new working and living conditions. In her study of late-nineteenth-and-twentieth-century textile workers in Manchester, New Hampshire, Hareven found that kinship networks in communities of origin were reinforced by the back-and-forth migration of individual members, and the transfer of resources. Following 'chain migration' routes, villagers who went to work in industrial communities spearheaded migration for other relatives by locating housing and jobs. Those who remained in the communities of origin often took care of aging parents and other relatives who stayed behind (Anderson, 1971; Hareven, 1982). Hareven found that despite the scale of the modern factory system, workers' kinship networks cushioned the adaptation of immigrant workers to new industrial working conditions. Kin acted as brokers between the workers and their industrial employers. Rather than disrupting kinship ties, migration often strengthened them and led to the development of new functions for kin in response to changing economic and employment conditions in response to the requirements of the industrial system (Hareven, 1982).

The Family's Interaction with the Process of Industrialization

An examination of the family's interaction with the process of social and economic change enables us to understand more precisely what occurred internally within the family and how such changes were accomplished on a societal level. It provides new insights into the process of industrialization and urbanization, into how labor markets functioned, and how industrial work processes and labor relations were organized. Historical research on the family has led to the rejection of simplistic models of social change, especially of modernization theory. How the family both initiates change and adapts to it and how it translates the impact of larger structural changes to its own sphere are crucial questions for the understanding of the process of social change.

The important principle underlying these questions is a view of the family as an active agent. The family planned, initiated, or resisted change; it did not just respond passively. Historical research over the past two decades, highlighting the family's role as an active agent, has led to revising questions such as "What was the impact of industrialization on the family?" to "What was the family's impact on the industrial system?" (Hareven, 1982, cf Goode, 1963). The question has been further cast into a more complex form: Under what circumstances was the family more able to control its destiny and to affect the larger social processes, and under what circumstances did the family succumb to declining markets, changing modes of production, business cycles, and other external forces?

The family had a central role in charting the transitions to various modes of industrial production by following diverse routes: from a rural economy to a protoindustrial or industrial one, or from a rural economy directly to an industrial one. In all these cases, while following its own priorities, when possible, the family facilitated the advance of industrialization by releasing the labor force needed for the newly developing factories and by organizing migration to industrial centers (Smelser, 1959; Tilly and Scott, 1978; Quataert, 1985). The family's interaction with the industrial system has received attention from studies of family production systems in artisanal and protoindustrial settings and the study of family and work in the context of large industrial enterprises.

Protoindustrialization was a household-based form of production in the countryside and in some urban areas in England, France, Belgium, Switzerland, and Austria, from the seventeenth to the nineteenth centuries that preceded the 'industrial revolution.' It was characterized by the production of goods in local cottages for a capitalist employer who sold the products in external markets. Rudolph Braun (who first identified these patterns in Switzerland) and other historians developed a model of demographic behavior they claimed was typical of 'protoindustrial' families. This consisted of earlier age at marriage, higher fertility, and delays in children's departure from the home, all of which were conducive to maximizing a family labor force. Marriage formed the key to the spread of the cottage industry, because it led to the formation of a new nuclear family unit, which was also a 'unit of labor' (Braun, 1974; Mendels, 1972; Medick, 1976).

In the 1980s and 1990s, the demographic model of protoindustrialization has come under criticism. On the one hand, scholars have questioned whether demographic behavior associated with protoindustrialization had been sufficiently widespread to warrant such generalizations. They found that demographic behavior in response to new economic conditions "differed according to the environment (i.e., land ownership, social structure, and inheritance) and the exact nature of the economic change which took place" (Gutmann and Leboutte, 1984: p. 589). Regional variation, interaction

with the local agricultural structure, as well as the type of cottage industry (whether weaving or spinning), made a difference (Mitterauer, 1992).

Like research on the family in protoindustrial regimes, the study of family in the factory system has provided considerable evidence documenting the family's role as an active agent in its interaction with the process of industrialization. Such research effectively undermined the theory of 'social breakdown' that had haunted sociology and social history. According to this notion, migration from rural to urban centers had led to the uprooting of people from their traditional kinship networks. The pressures of industrial work and urban life caused a disintegration of the family unit, and adaptation to industrial life stripped migrants of their traditional culture (Parsons, 1955; Wirth, 1938).

Historians and sociologists alike have challenged the theory of social breakdown, by providing contrary evidence. Neil Smelser, in his pioneer study of the family in the early stages of industrialization in Britain, documented the recruitment of entire family groups as work units in the early textile factories. Fathers contracted for their children, collected their wages, and were responsible for their performance in the factory. Entire families depended on the factory as their employer; the factories, in turn, depended on the recruitment of family groups to maintain a continuous labor supply (Smelser, 1959). Anderson documented a continuity of recruitment in family units and in the vital role of kin among workers in the textile industry in Lancashire, England, at least through the middle of the nineteenth century. The practice of family members working together in the factory was carried over into the United States, as the factory system developed there, and was still present among immigrant workers in the twentieth century. The very success of the early industrial system depended on the recruitment of labor along kinship lines (Anderson, 1971; Hareven, 1982). As mentioned above, Hareven's study of family and work in the Amoskeag Mills in Manchester, New Hampshire, has documented the active role of the family and the kinship group in relation to the industrial corporation. It showed that the family type most 'fit' to interact with the factory system was not an 'isolated' nuclear family, but rather one embedded in extended kinship ties (Hareven, 1982).

The functions that kin fulfilled in their interaction with the factory system were not merely archaic carryovers from rural society but a selective use of premigration patterns of kin assistance patterns in response to the needs dictated by industrial conditions. The encounter of immigrant workers with the modern factory system led neither to the abandonment of premigration family traditions, nor to a rigid adherence to them. Rather, the workers adapted their customs and social organization to the new conditions they confronted. In doing so, they addressed the factory system on its own terms. The family selected those aspects of its premigration culture that were most useful in coping with industrial conditions and adapted them to new needs. These patterns of selectivity called into question the linear view of social change advanced by modernization theory. Family behavior did not modernize at the same pace as workers' conduct in the factory. The family was both a custodian of tradition and an agent of change (Hareven, 1982).

Family Strategies

To better understand the family's role in these processes of social change, it is necessary to examine how families charted their strategies in relation to external opportunities and constraints. Family strategies involved both the decisions individuals or families made and the actual timing of such decisions in relation to opportunities and constraints. Strategies included, at times, calculated trade-offs in order to find employment, achieve solvency, buy a house, facilitate children's education or their occupational advancement, control or facilitate a child's marriage, save for the future and provide for times of illness, old age, and death. Strategies were part of a larger life plan. As people encountered new circumstances, they modified and reshaped their plans and strategies in the context of their own culture and traditions (Hareven, 1990).

As research on family strategies developed further, the concept also underwent important revisions. Under the influence of feminist historians, the question was raised: 'Whose strategies are family strategies?' This question is still part of an important research agenda about the process of decision making within the family, particularly concerning women's participation. Recent research suggests, though, that there may have been a considerable variation along gender lines and among family members in the forging of strategies.

Future Directions

The multidimensional research effort in family history has produced impressive results and identified new lines of investigation. Research still needs to pursue established topics that have not received sufficient attention, including the family's relationship to social space and a more systematic study of the family's relationship to religion, the state, and the legal system.

There is a need for more systematic studies of the 'edges' of family life, such as solitary individuals, orphans and foundlings, and the process of family breakdown through divorce or death and of family reconstitution through remarriage. A second direction is the forging of more systematic linkages between demographic behavior and household structure with internal family dynamics; a closer integration of the study of the household with nonresident kin; a more careful linkage of kinship and household patterns with various processes such as work and migration; and the relationship between demographic and family patterns with cultural dimensions.

In addition to this specific agenda, the larger questions of historical changes in the family over time still need to be explored systematically in several directions: First, if industrialization did not cause the emergence of 'modern' family behavior in Western Europe and the United States, what did cause it? One plausible explanation that has been advanced is the commercial revolution of the sixteenth and seventeenth centuries. This does not explain, however, the existence of nuclear household patterns in the Middle Ages. While Stone (1977), like Aries, dated the emergence of the 'modern family' in the late seventeenth and early eighteenth centuries, Shorter placed it in the late eighteenth, and early nineteenth centuries. Carl Degler (1980) dated the emergence of the American modern family in the late eighteenth or early

nineteenth centuries as well. Following in Aries's footsteps, Stone, Shorter (1976) and Degler have focused on the rise of 'affective individualism' as the major criterion of 'modern' family life. They generally agreed that the 'modern family' is privatized, nuclear, domestic, and based on emotional bonding between husband and wife, and between parents and children. The correlates of its emergence were the weakening influence of extended kin, friends, and neighbors on family ties and an isolation of the family from interaction with the community. There is some disagreement and, at times, lack of clarity about which class initiated these changes. Aries, Stone, and, more implicitly, Degler viewed the bourgeoisie and the gentry as the vanguard, while Shorter assigned a crucial role to peasants and workers.

Related to the emergence of the family as a private, intimate entity is the widely accepted interpretation that this transformation was based on the family's surrender of earlier-held functions of production, welfare, education, and social control to other institutions and its withdrawal into domestic privacy has become one of the standard clichés of family history and sociology. We need to understand the process by which these functions were transferred to other institutions. A systematic exploration of the family's relationship to public agencies and institutions – specifically institutions of education, welfare, and social control, after the transfer of its functions – will help historians escape the trap of viewing the family as an isolated domestic entity.

Historical studies in Europe in the 1990s have emphasized an integrated view of the family both as a private entity and an object of the state. *The History of Private Life*, under the general editorship of Philippe Aries and Georges Duby, which focuses primarily on French society, deserves particular attention. The fourth volume, *From the Fires of Revolution to the Great War*, edited by Michelle Perrot, presents the experiential history of the family in relation to public life. The authors view the family's private life and sexuality as inseparable from the state (Perrot, 1990).

As further research continues to emerge, it becomes necessary to develop a comprehensive model of change in family behavior that does justice to its complexity. The most important dimension still absent from studies of long-term changes in the family involves more systematic distinctions by social classes, rather than generalizing for the entire society on the basis of the middle class. We need a more detailed understanding of the historical process by which other classes adopted middle-class family behavior, if indeed that was the case, and of what class differences have survived such a process. How did patterns of family behavior that first emerged in the middle class transfer to other classes in society and by what processes? Equally important, at the end of that process, had rural and working-class families really adopted middle-class family forms, or did differences persist underneath apparent similarities?

The question about when and how change takes place needs to be raised again. Various strands of change in family history still need to be traced individually to the point of their culmination as visible transformations. The process is rendered more difficult by the fact that not all the strands undergo change at the same pace. As the family is not a monolith, different members within it may initiate change or accept change at different points. For example, women were agents of change in certain areas of family life, such as in the practice of family limitation, while men were innovators in others. Even children were innovators in certain areas. They may have brought literacy into the family, new perceptions of behavior they learned in school or new work habits and new technologies. Thus, when we examine the family's role in the process of social change, we need to differentiate among the respective roles of members within the family, in interacting with these processes. This is an important task for future decades.

Abstract

The practice of Family Therapy and its theoretical underpinnings have been evolving for more than 60 years. Family Therapy, Family Interventions, and Systemic Family Practice are in many parts of the world accepted as key components of mental health services. There is increasing evidence to support the value of systemic approaches and an increasing commitment from practitioners to develop and work from a sound evidence base. This article gives a brief overview of Family Therapy and other family interventions, and the theories informing their practice. Evidence for efficacy is examined and current applications are discussed.

The practice of Family Therapy and its theoretical underpinnings have been evolving for more than 60 years and Family Therapy, Family Interventions, and Systemic Family Practice are in many parts of the world accepted as key components of mental health services. There is increasing evidence to support the value of systemic approaches and an increasing commitment from practitioners to develop and work from a sound evidence base (Eisler and Lask, 2009; Carr, 2014a,b). This article provides a brief overview of Family Therapy and other family interventions, and the theories informing their practice. The evidence for their efficacy is examined and current applications are discussed.

The beginnings of Family Therapy can be found in the fields of both adult and child mental health. In the 1940s and 1950s there was an interest in the way in which communication within families might give rise to schizophrenia in a family member (Singer and Wynne, 1966). Although this idea has been shown to be erroneous, the focus on patterns of communication, including 'the double bind theory,' has been influential and added to our understanding of the way in which families can have profound effects on the mental health of individuals. Unfortunately the idea that there is a direct (often one way) relationship between family dysfunction and individual problems persisted for some time. However over the last 25 years there has been a growing awareness that this explanation is a serious over-simplification of a very complex process. In current practice, families are seen as resources and working partners rather than the main cause of problems. Genes, personality, life experience, social and economic environments, and health together with families and other relationships are joint contributors to both psychiatric illness and well being.

Work in the areas of child development, attachment, and adult mental health has highlighted the importance of family and other relationships in the development of good mental health (Rutter, 2006). Conversely relationship dysfunction can give rise, and contribute, to mental health problems such as depression, anxiety, attachment disorders, and phobias. In Child and Adolescent Mental Health there is unsurprisingly, a greater awareness of the importance of families, carers, and other systems around the child and the need to include them in any treatment plan. In the 1960s, Bowlby, among others, began to include parents in treatment. By the 1980s the profession of Family Therapist was developing in a number of countries and appointments of Family Therapists were being made in Child and Adolescent Mental Health Services. Family Therapy has now become established as one of the main evidence based treatments available to children, young people, and their families. In adult mental health the developments have been more uneven. This is understandable when the role of the family is less clear; however, the value of Family Therapy and Family Interventions has proved important in supporting families and engaging them in helping a family member with mental health problems. Systemic approaches are also helpful in working with complex professional systems and other care groups such as hostels and day centers.

What Is Family Therapy?

This is a more complicated question than it seems. Although the idea of the system being important is foundational, family therapy is broad based and contains many approaches to thinking about and working with families and other systems. Some approaches focus on working with patterns of behavior, others with beliefs or emotional attachments, and yet others with trans-generational influences. Some psychiatric problems are more likely to respond to one approach rather than another but there is also an emphasis on adapting the approach to best fit a particular family. Value is placed on engagement and collaborative working, both of which are increasingly accepted as key components of successful and ethical psychological treatments. Family Therapists also have a broad definition of the family and will pragmatically work with the most important people around a referred child or adult. This may involve seeing the whole family together, parts of the family (sub-systems), or the family without the referred patient. Decisions are made on the basis of who is available and the agreed focus of the work. Sometimes interventions may be made with other systems such as professional systems or friendship networks or, in Multi-Family Therapy, a number of families may be seen together (Asen and Scholz, 2010). Fundamental to Systemic Family Therapy is the idea that we are all affected by relationships with others and if the systems

around us work well and support recovery this will make a positive difference to outcome, The next section will contain a broad overview of the foundational ideas of current practice followed by a discussion of the evidence base of some of these approaches and an outline about how they may be used in practice.

Theoretical Overview

Systemic Family Therapy is concerned with the functioning of families and other systems and different approaches focus on particular aspects of systems. Early approaches were influenced by cybernetics and the idea of self-regulating systems. The focus was on mechanisms that moderated the dual aspects of change and stability. In this way problems were often seen as attempts to keep a system stable. For example, a young person with eating disorder may keep a family together by requiring family members to focus on an ill child because of fear that the family may break apart once child-rearing is accomplished. In this sense the problem is seen to perform a function for the system. There was also a focus on patterns of communication – for example, patterns which lead to escalation but do not resolve the problem (Bateson, 1972). Elements of both of these approaches are to be found in current systemic therapies but no longer is each seen as the 'answer' but one part of a complex jigsaw of cause, influence, and effect.

Provision of a context that allows for both change and stability is important as families help members to adapt to developmental and contextual changes. Family Life Cycle Theory (Carter and McGoldrick, 2004) influences all major approaches in Family Therapy. It is a way of encapsulating the interaction between family, wider contexts, and the developmental needs of individuals. It outlines the way in which all families have to adapt and change over time. Unexpected events such as untimely death, forced migration, or unemployment will impose extra demands. When the demands for change are too great or there are conflicting demands (such as need for adolescent independence when there are serious external threats) individuals may develop problems such as depression, anxiety, or substance abuse. Flexibility and adaptability are important aspects of individual resilience and they are equally important in families. Thus, those who are able to adapt their roles and responsibilities, beliefs, and behavior to fit new circumstances will be more resilient to adversity (Rutter, 1999).

The idea of circularity is another key idea in systemic work. This refers to the way in which patterns of behavior can become repetitive circular processes. The following example is influenced by attachment ideas which have been an important recent influence on Family Therapy. An anxious husband seeks reassurance from his wife who is preoccupied with work, which leads his wife to become irritated and to resist his demands which in turn makes him more anxious and more 'needy' which, in turn, is more intolerable for his wife who has a need to feel independent. This may be an oft-repeated pattern that can be described as 'stuck' and does not lead to any resolution or change. Meanwhile the husband's anxiety symptoms may lead to a psychiatric referral. Family patterns passed down from one generation to another may also be a factor in maintaining these unhelpful interactions.

Another fundamental idea is that what happens to one part of the system inevitably affects other parts of the system. In this way we are all impacted by what happens to those with whom we are in relationship and what we do affects them. Family therapy in child psychiatry began to develop because of observations that children in individual therapy were unable to move on because of the way their family behaved toward them. Approaches at this time were more influenced by psychodynamic ideas but over time these ideas have been used to a lesser degree in Family Therapy practice.

The 1960s saw the development of structural Family Therapy which focuses on the importance of clear organizational structures, roles, and responsibilities in families. This approach suggested that problems were most likely to develop when the structure of the family was unclear, relationships were either too distant or too enmeshed, or children were parentified. Sometimes individuals become 'triangulated' or caught up in the problems between others (perhaps a child caught up in parental conflict). As with family life cycle theory, criticisms were made that it presented a very narrow, white middle class view of family life. However the ideas are still very useful as long as account is taken of family differences including class and culture. Interventions are often carried out within family sessions with the aim of helping families to relate in more positive ways. For example where an adult daughter is caught up in the conflictual relationship between her parents, the therapist may encourage the parents to have a discussion while the therapist ensures that the daughter does not intervene. This allows them all to have the experience of communicating in a different way.

The same period saw the development of Strategic Family Therapy that focuses on stuck behavior patterns, natural resistance to change, and the need to devise creative solutions to encourage people to make those changes. It assumes that insight is not always possible and does not inevitably lead to change. In this approach between sessions family tasks are often set. The focus is change in repetitive behavior patterns. For example a therapist may ask a couple to 'put off' their daily arguments until after the evening meal and then to sit down and argue for 15 min. The idea is that if an argument is taken out of its usual context it may have a different flavor, some of the high emotion will be decreased and the instruction to do so may lead to some reflection and even rebellion! As time progressed concern grew about the possibility of this approach being manipulative but the ideas can be used in an open and transparent way with due care and attention to ethical practice.

Another approach that focuses on behavior change is Family Interventions in Psychosis (Lam, 1991). This has been shown to be an effective approach in reducing relapse rate for those who have developed a psychotic illness and focuses on psycho-education and reduction of high emotional intensity, especially negative and critical comments. This is a good example of the therapist taking a collaborative position and working with the family as a team in order to help a family member with serious mental health difficulties. In the early days of Family Therapy there tended to be a focus on the family as the cause for schizophrenia and other psychoses. Patients were seen as being caught in a 'double bind.' The double bind

was defined carefully as a contradiction within the verbal content of a message, or between the words used and the feelings expressed. In addition, the recipient of the message is not allowed to comment on the contradiction or leave the relationship (the doubling of the bind) (Singer and Wynne, 1966). At this point little account was taken of the effect on families of living with a member with serious psychiatric illness. Studies into the consequences of the discharge of chronic psychiatric patients into the community found that relapse rates were higher when the discharge was to close relatives (Leff and Vaughn, 1985). This led to the study of high emotional intensity as an important factor in relapse (Butzlaff and Hooley, 1998). National organizations were set up by relatives of patients – such as the National Schizophrenia Fellowship in the UK and the National Alliance for the Mentally Ill in the US. This further raised the profile of families who were often judged negatively or marginalized by mental health services. Research in the 1970s and 1980s showed that a program of psycho-education help, with reducing negative comments and increasing problem solving, reduced relapse from 50% to 20%.

During the 1970s and 1980s some important developments took place in Milan in Italy where the approach called Milan Systemic Therapy was developed (Boscolo, 1987). This approach highlighted the importance of beliefs as determinates of behavior, relationships, and emotions. The context for the development of these ideas was closure of large psychiatric hospitals and the need to treat people as out patients and involve their families. This approach developed questioning techniques (Fleurides et al., 1986) and encouraged the therapist to retain curiosity as they explored the connections between problems and relationships. Techniques included Socratic questioning similar to that utilized in cognitive behavior therapy but also included 'circular questions' which explored the connections between relationships, beliefs, and behavior. These questions were used to gather information about how the system worked, explore hypotheses, and also act as an intervention to help family members become observers of themselves and explore new ways of seeing things. This approach also gave rise to developments in team working and the use of a one-way screen through which team members observed the therapy session and had mid-way discussions with the therapist in order to share ideas and present alternative viewpoints. The next developments often called 'Post Milan' took a postmodern position and rejected simplistic cause and effect. More account was taken of the value of open dialogue in therapy, the exploration of meanings, and the evolution of new ideas. Therefore, for example, a depressed family member may come to be seen as bravely struggling against depression rather than as a failure. This will alter the way other family members relate and behave. This 'reframing' is a key intervention in a number of approaches.

Narrative approaches to therapy developed from the 1980s and focused on the way that all of us develop 'narratives' to make sense of the world and emphasizes the way in which those narratives shape the way we live our lives (Morgan, 2000). There is a particular focus on the way in which wider systems such as community, culture, professional systems, education systems, media, and so on contribute to, and shape those narratives. The role of the therapist is to help individuals, couples, and families look at alternative narratives which better fit their lives and help them to move forward. The process of understanding how narratives are formed challenges their truth and opens them up to examination. The therapist becomes a witness to new developments in the patient's life and celebrates and highlights positive changes, emphasizing the patient's personal agency in making the changes. An intervention from this approach, widely used with people with psychiatric illness, is 'externalization.' The illness is separated from the person by speaking of it as an external entity. Questions will be asked about how the 'anorexia' affects everyone's lives and there follows an exploration of the ways in which it has been possible to control 'anorexia.' The aim is to identify 'unique outcomes' which serve to question the assumption that the person is totally inhabited by the illness and is helpless. These unique outcomes are developed in order to generate useful tools to help reduce the power of 'anorexia.' A similar approach, used on its own or as part of an integrative approach, is Brief Solution Focused Therapy (De Shazer, 1985) which identifies and helps reinforce a person's own preferred ways of fighting symptoms. For example, someone might state that if their partner smiles at them in the morning it 'gets the day off to a better start.' The partner may be asked to smile even though they do not feel like it. Embedded within many of these approaches is the idea that a small change can have a beneficial ripple effect throughout the family.

These 'postmodern' approaches have led to therapy teams being used in different ways. They can be used in narrative therapy as groups of witnesses commenting on new developments in someone's life or perhaps as reflecting team who come into the therapy room and share different perspectives on the issues being discussed.

Open dialogue approaches in the treatment of serious mental illness (Seikkula, 2006) is a recent development. This approach involves family members and members of the professional network who meet together to talk. The assumption is that solutions will emerge out of the unstructured conversations. This has proved to be helpful at times of crisis and enables everyone including the patient to be heard and for new ways forward to be decided.

More recently Family Therapy has developed a greater interest in emotions and the way they are connected to beliefs, relationships, and behavior. Emotionally Focused Couple Therapy is an example of such an approach. It combines attachment ideas, communication coaching, and trans-generational ideas with systems theory (Johnson, 2004). Narrative Attachment Therapy developed by Dallos and Vetere has a similar focus.

Values and Ethics in Current Practice

Systemic approaches emphasize the importance of context in determining the way we live our lives and the practice of Family Therapy has of course also been influenced by the societal and professional contexts. The focus currently is on creating a strong therapeutic alliance (Escudero et al., 2008), working collaboratively with family members and other clients, and respecting individual aspirations. There is a strong focus on respect for, and taking account of difference in relation to gender, culture,

religion, ability, and other dimensions of difference (Flaskas et al., 2005). There is also a strong emphasis on working from a strength and resilience perspective and appreciating the capacity of family members to overcome most difficulties as they go through life. There is more humility about the fact that no approach works effectively with everyone. Systemic Psychotherapists work hard at understanding their own issues and experience and the way in which these affect their work. Experience can be a resource but at times may constrain the work and, for example, lead to an avoidance of certain questions or a fear of upsetting a particular family member. Many systemic psychotherapists do have their own therapy but work on the interface between personal and professional is usually done in groups as part of their course and not termed 'therapy.'

When a number of individuals have to be taken into account, the ethics of practice become more complex especially when there are power differentials and conflicting needs. There is a clear remit to prioritize those who are most vulnerable, and the safeguarding of children is a priority. Most people have a commitment to integrative working although some will focus on one particular approach. There is a clear requirement for Family Therapists to work within the boundary of their own training and skill and to consider other approaches and treatments which would be helpful as an alternative or adjunct to their work.

What Is the Evidence for Systemically Based Psychological Therapies?

Especially where psychological therapies are delivered in public sector services it is important to gain as much information as possible about their efficacy and more specifically which aspects of therapy are most useful and in what circumstances. Health economics assessments of approaches are now a common requirement. In a series of US studies it was shown that the medical cost offset associated with Family and Couple Therapy at least covered the cost of the therapy and sometimes exceeded it (Crane and Christenson, 2012). The links between childhood psychiatric disorder and adult disorder are well documented so that although this section is divided into adult and child, it is clear that this is more a reflection of the organization of services than the reality of life. Research into work with families is particularly complex because the focus is rarely exclusively on the referred patient. Measures into family functioning are not entirely satisfactory and can be cumbersome. The development of the SCORE measure of family functioning provides a new, easy to use, clinically based measure which will be of assistance in much needed research into Systemic Family Therapy especially in Child and Adolescent Mental Health (Stratton et al., 2014).

Depression and Anxiety

The incidence of depression and anxiety is high with almost a fifth of adults in the UK reporting signs of depression and anxiety. The condition is highly distressing for the person suffering from depression and also for other family members, including any children, In the UK the incidence of anxiety and depression in children is on the rise. Although current research indicates that Cognitive Behavior Therapy (CBT) is a preferred first line approach this does not work, or does not work sufficiently for everyone. Narrative reviews of controlled trials of systemic interventions for depression support the effectiveness of outpatient and inpatient systemic couples therapy, Family Therapy based on the McMaster Model, Emotionally Focused Couples Therapy, Behavioral Couple Therapy, Cognitive Marital Therapy, and Conjoint Interpersonal Therapy (Barbato and D'Avanzo, 2008). All of these approaches to Couples Therapy require fewer than 20 sessions and focus on relationship enhancement, mood management, stress reduction, and damage limitation for other family members.

Studies by Leff et al. (2000) and Lemmens et al. (2009) show that Systemic Couple Therapy is more effective than medication at 2-year follow up. Lemmens et al. utilized a mix of multi-family groups, couple sessions, and family sessions and found that the outcomes were much better than medication alone.

Early on in the history of Family Therapy there was an interest in the origins of psychosis and the possible ways family interactions could exacerbate problems. While it is clear that there is no straightforward causal link between psychosis and family interaction, work on family interventions in psychosis has shown the value of an approach which combines psycho education with lowering the levels of expressed emotion. Pfammatter et al. (2006) carried out a review of three meta-analyses of psycho-educational Family Therapy together with a new meta-analysis of the 30 best trials. They found that multimodal programs including both psycho-educational Family Therapy and medication led to lower relapse rates and less hospitalization.

Family based therapies have been shown to be effective with agoraphobia and panic disorder, and with OCD. Systemic interventions create a context in which families can support recovery and a forum within which family interaction patterns maintaining symptoms can be addressed (Renshaw et al., 2005).

Behavioral Couples Therapy is an established approach in working with people with alcohol problems. Typically, treatment includes a sobriety contract, help with problem solving, communication training, and relationship enhancement work (O'Farrell and Clements, 2012).

As the focus of this is psychiatric illness it is worth mentioning the role of Couple Therapy, Family Therapy, and mediation in the process of separation and divorce. The relationship stress associated with the process of divorce and separation and the risks for the mental health of children and future adults makes it important to consider the value of systemic approaches which not only work with the couple but also with the children. They will keep the needs of the children paramount and help parents to collaborate in creating the best outcomes despite their own strong emotions.

It is not surprising that family approaches have a significant part to play in the treatment of child and adolescent psychiatric problems. Although the differences in many studies are small the evidence for family interventions is growing, with a number of recent well designed and large scale studies. A number of recent reviews provide a general overview of the evidence for the field as a whole (Carr, 2014a,b) as well as for problem specific areas such as alcohol and drug abuse

(Hogue and Liddle, 2009), conduct disorder and delinquency, eating disorders, anxiety disorders, and mood disorders (Cosgrove and Chang, 2013).

With most problems the differences between Family Therapy and other active treatments are relatively small but with some there is consistent evidence of Family Therapy leading to better outcomes. This is particularly the case for behavior problems, youth offending (Sydow et al., 2013), and substance misuse (Tanner-Smith et al., 2013) where the evidence from around 30 RCTs provides clear support for the use of Family Therapy both in terms of outcome and engagement in other parts of the therapeutic program (Stanton, 2004).

Similarly, there is now compelling evidence for Family Therapy in the treatment of eating disorders (Couturier et al., 2013) with recent larger studies confirming its superiority in the treatment of anorexia nervosa in comparison with an adolescent focused individual therapy as well as its role in the treatment of bulimia nervosa.

For other problems such as anxiety disorders (including OCD), depression, or bipolar disorder there is evidence that family interventions are effective but the comparison with other treatments is less straightforward. Some studies have shown that where the parents themselves are anxious the family intervention may be more effective and there are data suggesting that even when there is no difference between changes in anxiety symptoms, the family intervention leads to greater changes in general functioning both at the individual and family levels (Khanna and Kendall, 2009). Two groups have evaluated Systemic Family Therapy for depression in children and adolescents and shown them to be effective in comparison with control (Diamond et al., 2002) and comparable to psychodynamic psychotherapy (Trowell et al., 2007).

Clinical Practice

Although there is good evidence that Family Therapy can be effective with a range of problems there has to be caution in translating research findings into practice. They can indicate useful ways to proceed but individual family factors have to be taken into account and culture, gender, and age can profoundly affect work with families. As previously explained, systemic work does not always have to include the whole family and there are times when this is contraindicated. Where there are safeguarding issues it is important to see a child or a young person on their own. High degrees of conflict may indicate that it is better to begin with some individual sessions and then move to family sessions. Sometimes particular family members do not want to be involved. A number of approaches to working with client groups have been manualized but these manuals are usually less specific than for some therapies and allow room for adaptation. For example, in work with conduct disorder in children the engagement process is particularly important and may take a number of sessions. Family work in this group tends to focus on family roles, clear communication, lines of authority, and problem solving. There is also an emphasis on embedding new learning in everyday life. Work with depression and self-harm in children and young people will focus on encouraging safeguarding and enabling communication of emotions as well as exploring attachment patterns. Work with eating disorders will begin by prioritizing refeeding and getting to a safe weight. It will involve 'externalizing' and helping parents to feel more skilled with their young person. Work with psychosis will usually involve some psycho-education and emotionally focused couple work for depression will focus on managing strong emotions and meeting each other's attachment needs.

The number of sessions is sometimes prescribed (often between 6 and 12) but some pieces of work go on for longer and there may be variable lengths of time between sessions. Engagement of all family members is always a crucial aspect of the work and very often the completion of a genogram will help to track information about the family and identify patterns over time. Family Therapy may be a treatment on its own or an adjunct to other treatments and can be useful in engaging clients and encouraging compliance with other approaches. It is a method that over many years has given to client feedback and collaborative working to identify what each family and family member finds helpful. There are a range of nonverbal interventions such as genograms, drawing, and timelines. When small children are in sessions play and art materials are used to ensure the child is involved in a session and able to communicate in a way that is age appropriate. Experiential techniques such as family sculpting or role-play may be used. Between session tasks, diaries and research tasks are also commonly utilized.

All psychiatric illness affects others and can be adversely and positively affected by those around the ill person. Family Therapy has a key role in helping recovery and lessening the risk of relapse, as also in limiting potential damage to other members of the family.

Family and Schooling

Abstract

Discontinuities between home and school experienced by children, following which research designs to study relationships between family and schooling are described. The main conclusions of empirical studies of relationships between family socioeconomic status (the most frequently used measure of family circumstances) and children's school learning are presented. Family characteristics that affect student achievement are conceptualized in terms of economic, cultural, and social capital. Home support initiatives relating to health and nutrition and home–school partnerships for families characterized by high rates of educational failure, and the response of schools to problems associated with socioeconomic disadvantage, are described.

There is an obvious difficulty in considering relationships between families and other institutions at a time when families across the world are changing rapidly and radically in their structure, functions, and internal dynamics. While some investigations have addressed aspects of those changes, much research on family–school relationships does not take account of them. Perhaps this research is more properly regarded as providing information about homes, which can encompass a variety of family types, than about families.

Up to relatively recently, the family took major responsibility for the care, education, and training of children. In it, children acquired skills to deal with day-to-day tasks, including those of work. During the Industrial Revolution, as work moved into factories and became more specialized and skilled, and knowledge accumulated, families could no longer provide children with required knowledge and skills, and the need for an institution dedicated to formal learning arose. Increases in migration and urbanization served to underline the need, and so in the nineteenth century, nations came to accept education and training in school as their responsibility.

Discontinuities between Home and School

While one might expect families and schools to play complementary and mutually reinforcing roles in children's education, they may not always do so because of differences in their goals, structure, demands, activities, values, and the competencies they foster. These differences will be experienced to a greater or lesser extent by all children as they move from home to school: from life in a small group to life in large groups; from an environment marked by informality and freedom in the use of time and space to one in which children are allocated to classrooms and seats and work to a daily schedule; from an environment in which relationships are intimate, continuous, and particularistic to one in which they are less familiar, more transitory, and universalistic; from an environment in which learning occurs in a natural and realistic context as the need arises to one in which learning is formal, decontextualized, deliberate, and conscious, taking place day in, day out, whether or not it seems to have any particular purpose (Kellaghan et al., 1993).

Most children will in time adjust to the demands of the classroom. The ease with which they do will probably be, at least to some extent, a function of the compatibility of practices in the developmental contexts of homes and schools. When differences between homes and schools are large, children may experience a serious dysfunction in socialization when they go to school, which will affect their ability to adapt and to learn. This may occur in the case of children living in lower socioeconomic status (SES) homes; children living in developing countries who attend Western-type schools; ethnic or language minority children; and children of immigrant families. Most home support initiatives are designed to help children in these situations bridge the gap between home and school.

Research Designs to Study Family and Schooling

Research on the family factors that influence children's scholastic achievement (knowledge, skills, competencies, usually assessed by standardized tests) and attainment (level reached in the education system, operationalized by qualifications obtained, highest grade completed, or number of years in the education system), much of it in the context of policies of providing equality of educational opportunity, has been carried out, mostly in industrialized countries, since 1900 in several disciplines: education, psychology, sociology, economics, and behavior genetics. A variety of designs have been used. A great many studies used cross-sectional surveys in which data on student achievement were correlated with data on families obtained at the same time. Some studies used a longitudinal design, collecting data at varying points in children's life cycles. Other investigations capitalized on the conditions provided in 'natural experiments' to examine the development of sibling pairs with varying degrees of genetic relatedness (monozygotic twins, dizygotic twins, full siblings) in various types of family.

The limitations of correlational studies in disentangling the effects of variables that are intercorrelated to make inferences about causality are widely recognized. Even when efforts are made in analysis to control for the influence of variables considered to be relevant, there is always the possibility that investigators will have failed to obtain information on key variables.

Alternative methodologies to the 'objective' quantitative approach of empirical studies adopted the view that since acts imply purposeful constructions by actors, they can only be understood from the actor's point of view. In this context, ethnographic and case study procedures have been used to explore individuals' interpretations of family–school relationships. The approach is supported by the findings of psychological research that perceptions of family supports are better predictors of personal adjustment than actual supportive behaviors provided by network members.

Family SES and Children's School Learning

In a great majority of studies of the relationship between family variables and children's school performance, a measure of a family's SES (or social class) was used to represent family influence. SES is a multidimensional construct, and studies have varied in the weight they ascribed to one or more of its three main indicators (parental income, parental level of education, and parental occupation) or to other aspects of the students' environment, such as family and community resources, which have received increasing attention in recent studies.

In modeling the relationships between SES and its indicators, SES is commonly considered to be a latent variable in the formative sense since it is determined by its indicators (which have no necessary relationships with each other) (see Edwards and Bagozzi, 2000). This contrasts with a reflective relationship in which variation among indicators is assumed to be determined by the latent variable (as is the case in classical test theory). Very different causal structures are hypothesized in the two models with the consequence that choice of model has implications for the content validity of a construct and the representation of structural relations between it and its components.

Not all studies endorse the view that the relationship between SES and its indicators is formative. For example, SES is treated as a latent variable with reflective indicators in the Programme for International Student Achievement (PISA) (OECD, 2010). It may be that a mixed model is required to describe the relationship. Thus, causality/determination would be perceived to flow from first-order constructs (income, educational level, occupation) to indicators (items in questionnaires or other indices) in a reflective fashion and from the constructs to a second-order construct (SES) in a formative fashion (as indicated by the arrows in **Figure 1**).

The following eight conclusions can be drawn from studies of the relationship between SES and student learning (Bornstein and Bradley, 2010; Sirin, 2005; White, 1982). First, SES is positively, but not very strongly, related to children's performance on measures of scholastic ability and achievement. Children from high SES homes tend to perform better than children from low SES homes. Second, the magnitude of the relationship between SES and student achievement is contingent on several methodological factors in studies: (1) the way in which SES was measured; (2) the unit of analysis for socioeconomic data (aggregated data produce greater effect sizes); (3) the source of data (relationships are stronger when parents provide information than when students provide it); (4) the achievement measure (single subject achievement measures, such as measures of mathematics or science achievement, exhibit stronger relationships than general achievement measures, such as grade point average or a composite achievement test). Third, differences in cognitive skills between children from varying socioeconomic backgrounds are in evidence before children enter school.

Fourth, the length of time a student spends in the education system (attainment) is a function of his or her family SES. This is so even for students of the same level of general scholastic ability. Fifth, when secondary school programs are differentiated, major selection in terms of socioeconomic background occurs at the point of differentiation. Students from high socioeconomic backgrounds tend to enter an academic type of program that will lead to third-level education, while children from low socioeconomic backgrounds tend to enter technical, vocational, or short-cycle programs. The effects of SES are stronger at earlier than at later transitions.

Sixth, SES is a stronger predictor of achievement of white children than of minority students in the United States. It has been suggested that this may be because neighborhood and school SES exert a stronger influence than family SES on student achievement in minority (especially African American) communities. Seventh, there appears to have been a decline in the strength of the relationship between SES and student achievement over the last three decades of the twentieth century. This may be due to improved social and economic conditions, an increased number of minority and urban students in more recent studies, or the use of more sensitive measures of social and economic circumstances.

Finally, international studies reveal large differences between education systems in the strength of the association between SES and student attainment and achievement. For example, Sieben and De Graaf (2003) found significant differences between 11 countries in family effects on educational attainment. In PISA 2009, the percentage of variance in the reading literacy scores of 15-year-olds explained by a measure of student socioeconomic background (based on parental levels of education and the presence of cultural and educational resources, including books, in the home) varied from a low of 1.8 in Macao-China to a high of 27.4 in Peru (OECD, 2010). The fact that the variation was greater in 'partner' (non-OECD) countries than in more industrialized OECD (Organisation for Economic Co-operation and Development) countries raises questions about the appropriateness of using the measures of achievement and SES in the former. If measures of SES have been found to be limited in their capacity to capture minority students' social and economic background in industrialized countries (Sirin, 2005), one would expect even greater problems when they are used in countries that are culturally very different and less well developed economically.

Familial Factors Affecting the Development of Children's Competencies and Dispositions

The consistent finding that children's development, including their scholastic performance, is related to their socioeconomic background has led to a large number of studies designed to identify the precise factors contributing to this situation. A significant finding of such research is that variables that

Figure 1 First- and second-order relationships between SES and its components.

describe the ethos and teaching styles of families, although related to SES, are better predictors of student learning than measures of SES alone. While studies of the relationship between SES and scholastic ability and achievement, when individuals are the unit of analysis, typically yield correlations of about 0.2, the correlations between the ethos and teaching styles of families and measures of student ability and achievement are 0.55 and higher (White, 1982). Thus, it is concluded that what parents do is more important than their status.

Familial factors that affect the development of children's competencies and dispositions that facilitate scholastic progress have been conceptualized in terms of three types of 'capital': economic or financial capital, cultural capital which relates primarily to the conditions that foster cognitive and scholastic development, and social capital which is primarily related to conduct, identity, social behavior, attitudes, and motivation. Though the three types may be considered separately, they are interrelated. This is evident when, for example, parents' expectations and encouragement are used in definitions of both cultural and social capital. Other aspects of the relationship are in evidence when social capital is considered to enhance cultural capital, or when cultural capital is considered convertible under certain circumstances to economic capital.

Economic Capital

Economic capital relates to the material, particularly financial, resources available to families and communities. Its absence constitutes poverty, which is reflected in an inability to provide the basic resources required to support children's development. Among the factors that may affect children's ability to attend school and to learn are hunger, malnutrition, and a variety of diseases. Differences in the health of children have been found to explain a significant portion of the achievement gap between social classes (CDC, 2002). This is so even in industrialized countries, but is more pronounced in developing countries.

The role of the home is perhaps most obvious in the early years of children's development when homes take care of children's physical needs for food, nutrition, and health. However, all homes may not do this successfully, due to either lack of resources or ignorance. Families and communities are often unaware of the effects of nutrition, in particular that poor nutrition affects student achievement (CDC, 2002).

Nearly half of children in the developing world are underweight or stunted; a third are infected with parasitic worms; and a similar proportion suffer from micronutrient deficiencies. Malnutrition is increasing in Sub-Saharan Africa. While it is decreasing in South Asia, that region still has the highest rates and the largest numbers of malnourished children. This all adds up to a picture in which hundreds of millions of children are affected by ill health and hunger in ways that have consequences for their education (Bundy, 2010).

Cultural Capital

In addition to taking care of the physical needs of children, homes also lay the foundation for children's school learning by fostering the development of language, self-concepts, interpersonal skills, values, and motivation to engage in the formal learning tasks of the school. These activities are facilitated by cultural capital which exists in three forms: (1) in embodiments of cognitive and noncognitive competencies that actively organize future experience and may be inherited through socialization or may be consciously acquired; (2) in an 'objectified' state in cultural artifacts (pictures, books, instruments); and (3) in an institutionalized state (academic credentials or qualifications). Language forms an important part of cultural capital since, in addition to being a means of communication, it provides, together with a richer or poorer vocabulary, a system of categories, which enables one to decipher and manipulate complex logical and aesthetic structures (Bourdieu, 1986).

Separate strands of research in education (Kellaghan et al., 1993) and psychology (Moos and Moos, 1994) have identified a number of behaviors and conditions in the family that may be considered expressions of cultural capital: (1) modeling (in use of complex language; in planning and organization to ensure that time and space are well structured and used; intellectual-cultural orientation in activities; moral-religious emphasis); (2) providing motivation and reinforcement (encouraging and rewarding school-related activities and independence in decision-making); (3) holding high academic aspirations and expectations; (4) providing direct instruction (guiding and supporting academic work; helping with homework); and (5) ensuring that the activities engaged in are developmentally appropriate.

Social Capital

In separate, but mutually supporting research in psychology and sociology, interpersonal relationships have been identified as another area in which the family's influence on children's development can be discerned. In psychology, the focus is on cognitive aspects of support (that incorporate expectations about how others will respond when assistance is needed) and on actual supportive behavior (Pierce et al., 1996). Sociologists, on the other hand, speak of social capital, which is perceived to inhere in formal and informal networks of acquaintance and recognition between and among individuals and organizations (Coleman, 1987). Three forms have been identified: (1) shared obligations and expectations; (2) useful information that is passed between members of a social network; and (3) a value or norm consensus between adults, coupled with a willingness to monitor behavior and enforce norms that control and shape children's activities. These conditions are seen as contributing to the development in children of basic attachments, attitudes, willingness to make certain efforts, and concepts of self, all of which work to children's advantage when they go to school. It may be, however, that empirical research has overestimated the effects of social capital variables because of failure to take account of the tendency of similar people to become friends with each other. A variety of individuals and organizations can act as sources of social capital: siblings, grandparents, and other members of the extended family, neighbors, churches, and various social and cultural groups.

Variation in Family Structure

Research on the effects of variation in family structure and function on children's school learning does not provide clear-cut findings, which is not surprising given the complexity and variety of the conditions being investigated. It is, for example, difficult to design studies that will isolate the effects of family circumstances (e.g., divorce, maternal employment, blended families, lone parenting) from the effects of many conditions frequently associated with these circumstances. One consistent finding, however, is that lone parenting is often associated with school problems for children when the parent (usually a mother) is young, financially poor, and poorly educated. Single motherhood reduces children's future life chances and, since the condition is more common among low-income mothers, it most likely contributes to the intergenerational persistence of inequality (McLanahan and Percheski, 2008).

Many studies report a low negative correlation between family size and scholastic abilities, achievements, and attainment, due probably to variation in the availability of familial resources (including parental attention) for each individual child. At any rate, increased spacing between children tends to reduce the decrement associated with increase in size. The impact of family size has been found to vary with cultural context and type of outcome.

Changes over time in family structure and activities, reflected, for example, in a reduction in the number of adults (in the extreme case, in a lone-parent family) and in a decline in the range of exchanges between adults and children, are perceived by some commentators as having had a negative impact on children's educational development (Coleman, 1987). The changes are represented as reflecting an erosion of social capital.

Home Support Initiatives

Policy interest in helping homes support their children's development increased in the 1960s in the United States with implementation of Head Start, Follow Through, and Title 1 programs in preschool and early elementary grades. Policy was in part a response to dramatic changes in the structure and functions of families, as well as to the cumulative findings of research that home environments and out-of-school activities contribute significantly to students' school learning. It also was a reaction to the limited success, despite considerable investment, of school-based efforts to raise significantly the educational achievements of children living in areas described as economically and socially disadvantaged. Home support initiatives have focused on health and nutrition and on building partnerships between homes and schools.

Health and Nutrition

It was in recognition of the important role of health and nutrition that school health (medical inspection) and school feeding programs were among the first social protection programs to emerge at the beginning of the twentieth century in industrialized countries. Such programs, with a focus on improving the quality of school meals, are almost universal now in high- and middle-income countries. In low-income countries, there has been considerable growth in national school health programs over the last decade, though their coverage is often limited and in many cases regressive, providing most benefits to urban elites.

Programs include provision of food to children; micronutrient fortification (vitamins and minerals, especially vitamin A, iodine, iron, zinc, folic acid); deworming; malaria control; HIV prevention and care; and promotion of hygienic practices. Key elements of programs that have contributed to success include a focus on education outcomes; collaboration between education and health agencies; consultation with stakeholders (community-based organizations, nongovernment organizations, faith-based organizations, parent–teacher

associations); and use of existing infrastructures (especially school-based management systems) (Bundy, 2010).

Home–School Partnerships

In the United States, there is a long tradition of involving parents and communities in children's formal education in, for example, parent–teacher associations. In Europe, the situation is more complex because of differences between countries in legal arrangements and ideology. However, in many countries, recent efforts, in some cases supported by legislation, go well beyond traditional parent–teacher associations in the role they propose for parents, involving them in curriculum decision-making and in teaching and learning activities in the classroom (e.g., as classroom assistants) or in the home (e.g., in developing children's skills in problem solving and language and in supervision of homework). Many of the efforts are directed toward families in areas in which children face economic, educational, and social problems, and are considered to be at risk of educational failure, school dropout, and intergenerational poverty.

As is the case with family-support initiatives in general, parent involvement programs are designed to improve the developmental capacity and educational options available to families. They are based on a variety of models and approaches, have few theoretical frameworks, and vary in the extent to which empirical evidence is available on their effectiveness. Most programs can be described as instrumental-technical, in that they are designed to provide parents with a range of skills that are considered relevant to their children's education, addressing one or more of the aspects of family environments that are considered to impact on students' scholastic performance. Alternative approaches are based on an interpretative paradigm which, in recognition of the uniqueness of parents' experience, attempt to facilitate them in interpreting and understanding that experience. Other approaches go a step further, again helping parents interpret their situation, but to do so critically in the context of presumed determining social structures and ideologies.

There is an enormous and varied literature on programs designed to help parents provide a more stimulating and enriched environment for children's cognitive growth (especially in the preschool years) and to teach and reinforce the concepts, skills, and attitudes required in school (see, e.g., Bornstein and Bradley, 2010; Epstein, 1991; Henderson and Mapp, 2002; Kellaghan et al., 1993). Programs can be categorized by the extent to which they focus on children's formal learning and teaching. In some, the focus is distal, for example, involving parents in governance and advocacy on behalf of the school, engaging in voluntary work at school, and fund raising. In other programs, reflecting research findings on expressions of cultural capital, the focus may be considered proximal in that they attempt to increase parents' involvement in their children's learning. Such programs encompass a variety of objectives: to develop parents' understanding that the home environment has a profound effect on the school learning of children; to develop parents' sense of efficacy and belief that they can exert positive influence on their children's educational outcomes; to develop parents' self-confidence in establishing a home environment that will provide rich learning experiences for children; to encourage parents to engage in a range of activities that will contribute to the development of children's learning (e.g., engage in conversation at an appropriate level; provide access to reading material/books); to assist parents to develop strategies designed to supervise children and monitor how they spend their time; to encourage parents to talk to their children about school and what they are learning and to discuss future plans; to demonstrate specific strategies that parents can use (e.g., how to interact with children in dealing with homework); and to invite and provide opportunities for parent-teacher contacts, for example, to discuss students' scholastic progress.

Research findings on the effects of a variety of home interventions and parent involvement programs indicate that efforts to help parents become stronger partners in their children's learning can have a significant impact on children's cognitive development and school performance. The greater the involvement of parents in proximal activities, the greater the impact on student learning. To cite just one example, assisting parents to become involved in their children's homework has been found to result in higher rates of homework completion, fewer homework problems, and, possibly, improved academic performance among elementary school children (Patall et al., 2008).

Efforts to increase the involvement of parents in their children's education are not limited to industrialized countries. Such efforts find encouragement in research findings from across the world that document a positive relationship between parental involvement and a variety of school variables. For example, in 26-country international reading literacy study, degree of parental cooperation was found to be the strongest of 56 predictors of school effectiveness (Postlethwaite and Ross, 1992). Parental engagement has also been associated with reduced grade failure and repetition (Mexico); increased teacher efforts (El Salvador, Nicaragua); and higher student achievements on national primary school examinations (Kenya), tests of language and mathematics (Colombia), and life skills and writing (Bangladesh) (Gertler et al., 2006).

While evaluations of individual initiatives to improve family involvement have reported a variety of effects on parents and children, it has proved difficult to identify the precise aspects of partnerships that are effective, or the conditions in which they are most effective, because of variation in the goals of programs, in the situations in which programs are delivered, in the actual delivery of services, and in the recipients of services, together with design, methodological, and analytic flaws in studies designed to evaluate the effectiveness of programs (see, e.g., Mattingly et al., 2002; van Steensel et al., 2011).

A number of problems associated with efforts to promote partnerships have been identified. (1) Despite rhetoric regarding choice, partnership, and parents' role as primary educators, many efforts mirror the traditional home–school power relationships that they were designed to alter. (2) In many cases, schools limit the involvement of parents, denying them any real input into the construction of 'shared understandings.' (3) Many approaches are based on an implicit view of parents as being inadequate in parenting skills, or as being 'hard to reach.' (4) Many parents are untouched by the

partnership, and remain distanced and alienated. (5) The extent of parental influence depends on parents' social, cultural, and material resources. (6) Strategies generally fail to reach fathers (Vincent and Tomlinson, 1997).

The Response of Schools

The considerable effort that has been invested in programs designed to assist families, in particular parents, in providing children with experiences that will support their school learning may seem to place the onus for change firmly on the family. However, few would deny that schools also have a role to play in helping children deal with any discontinuities they may encounter in bridging the gap between their home and community experiences and the demands of schooling.

Many commentators have pointed to the need for teachers to guard against stereotyping, low expectations, and generally negative attitudes when faced with children from socioeconomically disadvantaged backgrounds who come to school with poor scholastic readiness skills. But a need has also been identified for a more dynamic response from schools. This might involve a range of instructional strategies designed to improve student learning or what has been called 'culturally responsive teaching' or 'culturally relevant pedagogies' that include instructional interventions that serve as a bridge between home literacy and school literacy practices (see, e.g., Li, 2009). It has also been suggested that if school personnel are familiar with children's home backgrounds, they will become aware of the categories of meaning that children bring with them to school, and the competencies they have developed, which can then be taken into account in teaching. Language is a major resource in these activities since it can be used to encode relevant relationships and to point out important connections between contexts and tasks that children may not identify without assistance. When connections are verbalized and made explicit, children are helped to see relationships between tasks in different contexts and to appreciate how skills developed in one context (the home) can be applied in another (the school).

Conclusion

That family factors (including SES) are related to children's school learning is one of the most consistent findings of social science. This does not mean, however, that issues do not remain in understanding the nature of the relationship. Two issues, which merit further investigation, can be identified. One relates to the uniqueness of each child's experience in the home. The second is the complexity of relationships between families and schools.

Sufficient research evidence exists to challenge the assumption underlying studies of the relationship between family factors and student learning that key influences on children's development (e.g., general intellectual climate of the home, parenting style, parental encouragement for achievement, provision of books) are equally shared by children growing up in the same family. If this were the case, we would expect the children in a family to be more alike than they actually are. Behavioral genetics, in addressing this issue, while recognizing that certain aspects of children's genetic endowment and environment (inside and outside the home) are shared by children in a family, points out that other aspects are unique to each child, and that when genetic relatedness is taken into account, it is the nonshared aspects that contribute to variation in children's characteristics (Plomin and Daniels, 2011).

Identification of significant aspects of nonshared environments, however, has proved elusive. Some systematic sources of differences within families, such as birth order, gender, sibling interaction, and differential treatment by parents, are obvious enough. However, they have not been found to account for a great deal of variance in children's school achievements. Neither have unsystematic stochastic development processes; the impact of single environmental events tends to be very small.

Most studies of relationships between family factors and students' school learning fail to take adequate account of how schools and families interact. Other research findings, however, should serve to underline the complexity of the interactions. First, family background (including SES) helps determine the kind of school and classroom environment to which a student will have access. Schools attended by students from lower socioeconomic backgrounds are likely to have more limited resources and less experienced teachers. Second, family background influences the quality of the relationship between school personnel and parents, particularly access. Third, teachers may have lower expectations for, and negative attitudes toward, students from lower socioeconomic backgrounds. Fourth, in school, student achievement will be negatively affected by the presence of increasing densities of students from lower socioeconomic backgrounds (social context effect). This situation will be exacerbated if students are tracked/streamed at an early age on the basis of measures of achievement or scholastic ability. Greater understanding of these issues could have important implications for addressing problems that can arise in the family–school interface and in the design of strategies to address them.

Abstract

In this article, I discuss focal interconnections between family and work. First, I outline the ways in which labor market participation is stratified by family statuses, depending on marital status, presence, and age of children, from an international lens. Second, I discuss how family and work roles may interact negatively, resulting in what scholars refer to as 'work – family conflict.' I discuss recent literature on work – family conflict, including key definitions and prevalence rates cross-culturally, as well as the health, family, and work-related antecedents and consequences of this modern-day stressor.

Introduction

This article considers a fundamental subject of family and work. That is, the interaction and conflict between these two role sets. Generally referred to as 'work – family conflict,' the negative interaction of competing demands associated with work and family roles can result in deleterious health, family, and work-related consequences. In this article, I first outline how labor market patterns vary by marital and parental statuses, before discussing in detail the topic of work – family conflict. I dedicate most of this article to outlining key definitions related to the topic of work – family conflict, along with its prevalence rates, antecedents, and consequences. **Figure 1** provides a visual overview of my discussion. In closing, I identify three previously neglected areas of research for the advancement of work – family scholarship.

Labor Market Patterns and Family Statuses

Labor market patterns vary widely depending on family statuses. For example, in some countries married individuals are more likely to be employed, compared to the unmarried (Bureau of Labor Statistics, 2011; Statistics Canada, 2011). In most countries, women without children or with older children are more likely to be employed full time, compared to women with younger children, who tend to work fewer hours, if at all (Solera, 2009). These trends depend on geographical region, however. I highlight key patterns in the following section with a concentration on gender differences in single and married parents' labor market participation.

Canada and the United States

As of May 2014, the labor market participation rate in the United States was around 63% (Bureau of Labor Statistics, 2011 http://www.marketwatch.com/story/us-labor-force-participation-rate-falls-sharply-in-april-2014-05-02). This value was slightly higher in Canada during that same time (Canadian Labor Force Survey, 2014). Many of these workers come from dual-earner families. A recent U.S. study reports that in close to half of married-couple heterosexual families (with and without children), both the husband and wife work. In approximately 20% of these same families, the husband is the only spouse working, whereas in 8% of these families the wife is the only spouse working (Bureau of Labor Statistics, 2014). These patterns are similar to reports from Canada (Ferraro, 2010).

Among families with children, over 85% have at least one parent working for pay. However, the rates of participation tend to be less among single parent households, and vary by gender. For example, among single mothers in the United States, 68.2% are employed, whereas 81% of single fathers are employed. Similar patterns are observed in Canada: single fathers are more likely to be employed; however, single mothers are slowly increasing their labor market participation – from 67% in 1995 to 80% in 2005 (Luffman, 2006).

Additional differences in labor market participation can be found among mothers in the United States and Canada, depending on children's ages. For example, the labor market participation rate overall for mothers with children under the age of 18 is approximately 70%; however, participation rates are lower among those mothers with a spouse present.

Mothers with younger children in the United States are less likely to be employed compared to those with older children. In 2013, the labor market participation rate for mothers with children under 6 years was 64%, compared to a participation rate of 75% for those mothers whose youngest child was 6–17 years old. Among mothers with infants, 57% participated in paid work during this time. These figures have risen, compared to previous years (Lavery, 2011).

Similar trends are documented in Canada, where the number of women in the labor force with children under 6 years grew from 31.4% in 1976 to 67.8% in 2012 (Statistics Canada, 2013). Canadian statistics, however, suggest that single mothers are less likely to be employed compared to mothers in married-couple families, albeit this gap has decreased over the past two decades. This difference in participation rates is most apparent among those with younger children: in 2009 only 45% of single mothers with an infant at home were employed, compared to 67% of married mothers (Ferraro, 2010).

Europe, Asia, and Australia

The patterns of employment in Europe, Britain, Asia, and Australia vary somewhat compared to those of the United States and Canada, especially with regards to mothers' employment. Recent statistics suggest that the number of single mothers in paid employment in Eastern European countries is greater than married mothers in most countries, specifically in

Figure 1 Theoretical model of work–family conflict antecedents and consequences.

the Slovak Republic, Spain, Luxembourg, Italy, and Greece. The difference in participation rates hover around 20%, and are likely due to levels of financial support provided by the state to single mothers. Countries that provide greater support tend to report fewer single parents in paid work, such as in Australia, Ireland, or the United Kingdom. A recent report on all single parents suggests that employment rates among this group are highest in Denmark, Iceland, Japan, Luxembourg, and Sweden and lowest in New Zealand, Turkey, and the United Kingdom (OECD, 2013).

Labor market participation rates across these countries also vary by parental status and the age of children, similar to Canada and the United States. Parents with older children are more likely to be working full time, compared to parents with younger children. The majority of parents with children older than 6 years work full time (30 h or more per week), whereas the majority of parents with at least one child under 6 years work part-time (less than 30 h per week). There are exceptions among single parents with younger children, who are more likely to work full time, again, depending on the level of state support afforded to sole-parent families (Eurostat, 2012).

Combining Family and Work: Conflict and Consequences

Greater numbers of parents – both married and single – in paid work across various geographical regions have led to growing experiences of work – family conflict. Work – family conflict refers to "a form of inter-role conflict in which the role pressures from the work and family domains are mutually incompatible so that participation in one role [family] is made more difficult by participation in another role [work]" (Greenhaus and Beutell, 1985: p. 77). Work – family conflict is considered bidirectional, including when work interferes with family (work-to-family conflict), or when family interferes with work (family-to-work conflict). Work – family conflict may be synonymous with work – family interference and work – nonwork conflict (Greenhaus et al., 2006). The combination of work and family can also lead to positive experiences, or what has been called 'work – family facilitation.' Defined as "the extent to which participation at work (or home) is made easier by virtue of the; experiences, skills and opportunities gained or developed at home (or work)" (Frone, 2003: p. 145). Similar to work – family conflict, work – family facilitation is bidirectional, and can be initiated by either domain. Despite recent attention to this topic, the details of work – family facilitation are beyond the scope of this article.

Work – family conflict may occur as some combination of time-, strain-, or behavioral-based conflict across competing role sets. Time-based conflict reflects the incompatibilities between work and family based on objective 'time' restrictions to one domain. Simply put, time spent in one domain makes it difficult to fulfill time obligations in the other domain. Strain-based conflict refers to strain experienced in one domain that carries over and interferes with responsibilities in the opposite domain. Behavioral-based conflict reflects processes by which behaviors in one domain restrict or contradict behaviors in the other domain, resulting in conflict. For example, leadership roles in the workplace are often characterized by assertiveness, aggressiveness, objectivity, and achievement. These behaviors may contradict family role expectations of the nurturing, caregiving, comforting spouse and/or parent, leading to greater conflict (Greenhaus and Beutell, 1985).

Prevalence and Consequences of Work – Family Conflict

Using similar definitions to those outlined previously, researchers have found moderate to high reports of work – family conflict, internationally. A recent Canadian study on the topic highlights that over 30% of Canadians report high work-to-family conflict, while approximately 40% report at least moderate levels (Duxbury and Higgins, 2005; Duxbury et al., 2008). When asked about the extent to which family life interfered with work life, 43% of this same sample reported high conflict across these domains.

American-based studies report similar findings, including the National Study of the Changing Workforce (Galinsky et al., 2008). Experiences of work – family conflict have been increasing among Americans – especially males. In 1977 only 34% of men reported work – family conflict, whereas 49% did in 2008. These values are higher among fathers in dual-earner households, 60% of which report some to high exposure to conflict today (Aumann et al., 2011).

Reports of work – family conflict in other parts of the world vary depending on the cultural context, with emphasis on the prevalence of dual versus single-earner families, and national-level work – family policies. For example, work – family conflict may be less prevalent in countries with more affordable child care or more gender egalitarian states, such as in Scandinavian or Nordic countries. Alternatively, parts of Asian and Middle Eastern countries that uphold more traditional family models of the male breadwinner and female domestic provider may report less work – family conflict, given the separation of domestic and economic spheres in these contexts (Gornick and Meyers, 2008). Europeans, on average, report similar work – family conflict levels as Canadians and Americans. A recent study by the EU found that over 25% experienced some form of work – family conflict. These figures are particularly high among women, where over 90% reported at least some pressure in either direction (European Agency for Safety and Health at Work, 2012: p. 2; see Kotowska et al., 2010; for the study details).

The consequences of work – family conflict are also well documented internationally, and generally fall under three typologies: individual health, family, and work-related outcomes (Bellavia and Frone, 2005).

Health-related consequences of work – family conflict include psychological distress, depression symptoms, and overall mental instability (Frone, 2000; Mirowsky and Ross, 2003). In fact, some find that work – family conflict is among the leading causes of psychological distress among North Americans (Young and Schieman, 2012; Young et al., 2014). Others have found positive associations between work – family conflict and anxiety, poor physical health, substance abuse, and negative emotions, such as guilt, exhaustion, shame and anger (Duxbury and Higgins, 2005; Hochschild, 1997; Korabik et al., 2008; Schieman, 2006; Simon, 1995).

Family-related consequences of work – family conflict include spousal disputes, reduced marital satisfaction, family distress, family alienation, and problems with children – including social, mental, and academic outcomes (Frone et al., 1992; Milkie et al., 2009; Senecal et al., 2001). Both family-to-work conflict and work-to-family conflict have been shown to negatively affect family outcomes of these types. Family-related tardiness and absenteeism, reduced emotional support, and problematic parenting are also shown to result from work – family conflict (see Bellavia and Frone, 2005).

Work-related consequences of work – family conflict include factors such as reduced job satisfaction (Bruck et al., 2002), increased job distress (Behnson, 2002), and positively predicts turnover intentions and absenteeism (Alsam et al., 2013; Bellavia and Frone, 2005). Some scholars also find that work – family conflict can reduce organizational commitment, overall (Greenhaus et al., 2006).

Theories/Perspectives of Work – Family Conflict

There are several theories used to explain the processes of work – family conflict. Among the most well-known is *role conflict theory*, which is traditionally rooted in role theory. Role theory suggests that individuals occupy a variety of roles on a daily basis. These roles may be inherently incompatible, given that they comprise various time and behavioral expectations. The clash between obligations results in what others have called 'interrole conflict.' Others adopted this theory in application to work – family conflict. Simply put, individuals experience work – family conflict when attempting to simultaneously occupy or engage in both types of roles (Greenhaus and Beutell, 1985; Kahn et al., 1964).

Demand-resource models have also been used to explain the antecedents and processes of work – family conflict. Demand-resource models suggest that the focal determinants of work – family conflict include the demands and resources at home and work (Bakker and Geurts, 2004; Voydanoff, 2007). For example, greater work and family demands, including job pressures, work hours, or number of children may increase work – family conflict compared to otherwise. Similarly, greater work and family resources, such as work flextime, schedule control, a supportive spouse, or paid domestic help may decrease work – family conflict (see Bellavia and Frone, 2005; Voydanoff, 2007; Young, 2011).

Other scholars further delineate work/family demands and resources as either 'within' or 'between' domain. Within-domain demands/resources are specific to work or family, respectively. Examples include generalized job pressures and in-house child care obligations. Between-domain demands/resources refer to those which can transfer and disrupt or aid demands in neighboring spheres. An example of a between-domain demand might be contact from supervisors at home. Alternatively, a between-domain resource could be job flexibility, because it provides individuals the temporal and spatial ability to simultaneously engage in work and family activities (i.e., taking work home; multitasking). Thus, while within-domain demands might reduce the time available for opposite domain-expectations, between-domain demands/resources might increase the extent to which work and family obligations interact (Voydanoff, 2007).

The distinction of within and between-domain demands/resources relates to a third, more recent perspective of work – family conflict processes: border/boundary theories. *Border/boundary theories* try to isolate the conditions that lead to the blurring of boundaries between work and family domains (Clark, 2000; Nippert-Eng, 1996). From this perspective, work and family obligations are not always incompatible and at

times may overlap or blur, complicating work – family interactions. This theory focuses on the continuum of overlap between work and family – ranging from total segmentation to full integration of spheres. **Figure 2** presents a visual representation of this idea, as outlined by Clark's (2000) version of Border Theory. The greater the integration, the greater the work – family conflict experienced.

To help explain these processes, border/boundary theories draw upon terms of *flexibility* and *permeability*. 'Flexibility' refers to the degree that an individual's work responsibilities can be completed outside the expected spatial and temporal parameters of the workplace. In other words, flexibility refers to "the extent to which a border may contract or expand, depending on the demands of one domain or the other" (Clark, 2000: p. 757). Likewise, 'permeability' entails "the degree to which a role allows one to be physically located in the role's domain but psychologically and/or behaviorally involved in another role" (Ashforth et al., 2000: p. 474).

It may be that permeability and flexibility help facilitate transitions between roles. However, they may also weaken the work – family boundary and influence role-blurring activities like multitasking on work and family activities, or working at home – each of which may contribute to work – family conflict (Clark, 2000; Olson-Buchanan and Boswell, 2006). Scholars refer to this as the *role-blurring hypothesis*, which predicts additional role-blurring activities, and therefore greater work – family conflict among those who experience greater integration, and whose work – family border is more flexible and permeable (Schieman and Young, 2010).

A final perspective of work – family conflict borrows from mental health scholarship in order to conceptualize work – family conflict as a *chronic stressor*, defined within the Stress Process Model (Pearlin et al., 1981). This perspective establishes a link between the experience of work – family conflict and the idea that it is embedded in broader social origins, including social statuses, biography, and social contexts (such as the neighborhood, workplace, etc.). These contexts affect the meaning of the stressor to the individual. Chronic stressors are also unique in that, by definition, they have dual objectives and subjective elements (Wheaton, 1999); whether or not there is an objective basis for the stressor, the "perception of it operates as a stressor" (Wheaton, 1997: p. 60). In the case of work – family conflict, the antecedents and consequences of perceived versus actual conflict between work and family differ. Objective influences, like work hours or child obligations, may lead to specific instances of time-related conflict. Yet, the social roles individuals assume and the immediate context in which they find themselves may

influence whether they perceive these situations as conflictual and problematic. From this view, the subjective component of work – family conflict and its consequences may be sensitive to alternate antecedents, such as the social and psychological context in which one finds themselves (Young and Wheaton, 2013: p. 482).

Commonly Documented Influences of Work – Family Conflict

Within these various theories there are standard sets of work – family conflict antecedents reported. *Work-related antecedents* – including work-related demands and resources – are more strongly associated with work-to-family conflict compared to family-to-work conflict (Byron, 2005). Work-related demands that tend to increase work-to-family conflict include work hours, job pressures or demands, role ambiguity, work dissatisfaction, or stress, and interpersonal conflict with coworkers or supervisors. Time spent at work and job pressures tend to be the most common predictor of work-to-family conflict (Schieman et al., 2009; Michel et al., 2010). Essentially, greater objective expectations placed upon an individual increases the likelihood that work will spill over and disrupt activities in the family sphere.

Work-related resources, alternatively, tend to decrease work-to-family conflict. Resources relate to job control, support, and rewards (Karasek, 1979: p. 289). Supportive coworkers and supervisors may provide instrumental and emotional support when dealing with work-related demands. Despite this assumption, evidence is mixed. Some researchers suggest that the availability of supportive supervisors and coworkers reduces the deleterious effects of work demands on work – family conflict, while others find no significant effect, or find that support actually increases the effect of demands (Ayman and Antani, 2008; Cooper et al., 2001; Wallace, 2006).

Job control reflects schedule flexibility, decision-making latitude, supervisory authority, and/or autonomy. Job control essentially allows individuals to dictate when, where, how, and what work is performed (Karasek, 1979). The ability to manipulate one's work demands to meet necessary family demands reduces experiences of conflict between the two spheres. As posited in the job-demand/resource model, job control fosters flexibility and the efficacious completion of responsibilities (Bakker and Geurts, 2004). Evidence of the advantages of job control for work – family conflict, however, is mixed. What constitutes work-related resources has been problematized among scholars, more recently. Current research highlights that so-called resources may in fact act like 'demands' that might increase rather than decrease work – family conflict (Schieman and Young, 2010). Control over work may allow individuals to more easily engage in role-blurring activities, which can increase permeability between work and family domains, and increase work – family conflict levels.

These findings closely mirror the associations found between job rewards, such as earnings and authority, and work – family conflict. Higher earnings and greater authority might help offset work demands, thereby reducing interference with family life. However, more rewarding jobs often come with greater control and more demands – both of which have been shown to increase work – family conflict (Schieman et al., 2009).

The workplace itself – including its policies and culture – may also influence experiences of work – family conflict. Family-friendly policies provide greater opportunities for employees to integrate work and family roles by offering flexible work schedules, job sharing options, on-site child care facilities, and paid family leave. However, the use of these policies by employees, and therefore their effectiveness, depend upon the workplace culture. More traditional workplace cultures might penalize workers for using the said policies, compared to more family-friendly workplaces. Consequences endured by workers may include reduced pay, or promotion opportunities. Thus, polices may be ineffective in reducing work – family conflict unless coupled with a family-friendly culture that encourages employees to take advantage of such opportunities (Thompson et al., 1999).

Family-related antecedents are more strongly associated with family-to-work conflict, compared to work-to-family conflict. These predictors can also be divided into demands and resources. Family-related demands might include number of children, presence of young children, time spent on child care and household chores, marital dissatisfaction, or spousal disputes, to name but a few (Michel et al., 2010; Young et al., 2014). Researchers have also documented the deleterious consequences of family role ambiguity for work – family conflict (Carlson et al., 2000).

Family-related resources can be categorized into physical and emotional resources. Physical resources comprise access to safe, affordable child care facilities, quality schools, convenient work locations in proximal distance to home (Mirowsky and Ross, 2003; Voydanoff, 2007). Emotional resources refer to the support provided by one's spouse and other immediate or extended family members (Frone et al., 1997). As might be expected, the absence of these types of supports may also constitute demands.

Experiences of work – family conflict may also vary depending on *sociodemographic characteristics*, including individual's gender, age, and socioeconomic status. Men and women, for example, have been shown to report comparable levels of conflict. This is likely because of men's growing reports of family obligations over the years, at least in North America (Aumann et al., 2011).

Despite what might seem like a convergence of quantitative reports of work – family conflict among men and women, the experience of such conflict might still vary by gender. Robin Simon – a gender and mental health scholar – explains that this might be the case since men and women attribute different interpretation of how work and family roles intersect (1995: p. 183):

> [h]istorically, the meaning of work and family roles has differed for males and females, and there has been greater interdependence between work and family obligations for men than for women. Whereas men's family roles largely involved economic support, women's family roles were based on emotional support and nurturance.

Because women's work and family roles are considered more independent, conflict between them may be more

problematic, compared to men's roles, which seem overlapping (i.e., the contribution to the family is in fact financial provision itself). Different interpretations of how work and family fit with one another can influence experiences of interaction between them.

Work – family conflict experiences also vary across the life course. Parents with young children experience the greatest work – family conflict (Mirowsky and Ross, 2003). This situation is mostly applicable to middle aged individuals (i.e., approximately, 20–40 years old, depending on national context). For example, the average childbearing age for women in North America is between 25 and 30 years old (Mathews and Hamilton, 2009; Milan, 2008). Younger and older people are less likely to have children living at home, and are also less likely to be working (Schieman et al., 2001).

Socioeconomic status also predicts variable work – family conflict experiences. Research has concentrated on either side of the spectrum – the poor and the professional. Families who are less off financially may hold variable work schedules, in precarious positions, with few benefits or job rewards. These individuals must work many hours to earn a living wage. This type of situation makes it difficult to negotiate family schedules, child care, and other nonwork-related obligations. The worst affected tend to be single mothers, with few financial resources, because they often lack emotional and instrumental support from others (Williams and Boushey, 2010).

On the other end of the spectrum, are higher socioeconomic status professionals. In most developed countries, there has been a growing emphasis on working longer hours among higher status occupations. The average American family, for example, worked 11 h more per week in 2006 compared to 1979 (Gornick and Meyers, 2008). Higher status positions are also associated with greater flexibility, autonomy, and control. All of these features can lead to what Schieman and colleagues (2006) refer to as the 'stress of higher status': higher status positions require longer hours and more demands, coupled with more job control and flexibility to meet these demands. As discussed previously, the combination of high demands and control can result in more work – family conflict, since it leads to greater permeability between work and family borders (Clarke, 2000).

Thus, the poor and professional might experience similar levels of work – family conflict. The difference is the extent to which each is free to choose the amount of interference across domains; the poor have less choice than the professional. Moreover, professionals maintain the financial means to offset these conflicts, and their deleterious consequences.

Related to the other antecedents mentioned thus far, marital and parental statuses influence experiences of work – family conflict, as well. Single parents, for example, endure greater work and family demands and have fewer family resources to draw upon compared to married couples or individuals in extended family households (Duxbury and Higgins, 2005). There may also be differences between married and cohabiting couples and unattached individuals. For example, researchers argue that the family domain and its associated demands can be less salient to cohabiting couples (Nock, 1995), which may result in lower levels of conflict between role domains. Moreover, compared to coupled parents, unattached individuals may experience less work – family conflict because they have fewer family-related demands that could potentially conflict with their paid work responsibilities (Byron, 2005).

Survey Measures of Work – Family Conflict

Research in the area often measures work – family conflict through quantitative surveys using a series of Likert items. Separate sets of questions are asked to measure work-to-family conflict, and family-to-work conflict. For example, to assess the extent of family-to-work conflict, respondents are asked how often in the past 3 months "Did your family or personal life drain you of the energy you needed to do your job?," "How often did your family or personal life keep you from concentrating on your job?," "How often did you not have enough time for your job because of your family or personal life?" (Bond et al., 2003). Similar questions are asked to assess work-to-family conflict, but revised accordingly. Separate scales are then generated from each set of questions, respectively.

Despite the rigorous validation of these items, they still have flaws. For example, some scholars point out that the frequency-based responses offered may be too vague, and do not identify whether an answer of 'very often,' for example, refers to daily or weekly experiences. This problem may be remedied by asking respondents to report the number of times they experience said conflict over some designated period; providing additional response categories to capture more detailed responses (i.e., 3–5 days per week, 6–7 days per week; or, the use of time-diary methods to track individuals' behavior hourly, daily, or weekly) (Bellavia and Frone, 2005).

Directions for Future Research on Work – Family Conflict

Despite progress on the topic of work – family conflict to-date, there is much research to be done. Work – family conflict is not an isolated experience, and instead, may impact surrounding others, including family members and coworkers/supervisors. Research, however, has focused mostly on consequences of work – family conflict from an individual-level, rather than from a dyadic, family, or organizational-level. Research on the crossover stress of work – family conflict to others is growing (Bakker et al., 2009; Young et al., 2014). However, the mechanisms through which these processes unfold, and the long term consequences crossover stress has for others, remain unclear. Researchers must ask broader questions about how parents' work – family conflict affects children throughout the life course – from childhood to adulthood. Scholars must also address how the work – family conflict of one spouse impacts another's day-to-day routines and mental health. Finally, studies of workplaces must further question how work – family conflict experiences affect dynamics among coworkers at an individual and group-level. These sorts of studies would help clarify the broader impact of work – family conflict on society, more generally.

A second neglected area of research includes studies on the contextual effects on work – family conflict – specifically the impact of residential neighborhood and community contexts. An emphasis on these areas complies with current calls for research. For example, Voydanoff highlights that "… few studies have examined the relationships of most interest … that is, the effects of community demands and resources on work-family conflict …," and concludes that "… proposed relationships regarding the role of community demands, resources, and strategies require examination through studies that are methodologically sound and that incorporate a range of community characteristics" (2005: p. 591). While some scholars have begun to address this gap (Voydanoff, 2007; Young and Wheaton, 2013), much more is needed to effectively advance literature on work – family conflict.

Finally, the definition of 'family' in the phrase work – family conflict must expand to include alternative family forms and activities outside the traditionally defined nuclear family. Work – family conflict is largely associated with the modern image of the dual-career couple with young children. However, unmarried nonparents across the globe also experience work – family conflict, based on the obligations from others in one's social network, like extended family members, friends, and neighbors. Moreover, the definition of what constitutes family should be inclusive of alternative family forms, such as same-sex couples with and without children. Research on work – family conflict – including definitions and research methods – must evolve to encompass these less prevalent experiences.

Summary

This article considered a central topic related to family and work; namely, the conflict that arises when individuals experience competing demands between these two role sets. 'Work – family conflict,' as it is commonly referred to in the literature, may be experienced as time-, strain-, or behavioral competition between spheres, and is considered bidirectional in nature. Work-related antecedents are more strongly predictive of work – to family conflict, while family-related antecedents are more strongly predictive of family-to-work conflict. Multiple theories have been used to explain the complex processes of work – family conflict, including more traditional views of role conflict theory, and recent views of border-boundary theories and the Stress Process Model. Work – family conflict may also vary depending on a number of sociodemographic features, including gender, age, and income. The topic has become of focal interest to work – family scholars in recent decades, as well as health researchers, as a result of the documented deleterious consequences arising from this modern-day stressor. Yet, despite the plethora of scholarship on work – family conflict to-date, researchers have neglected to consider the impact of work – family conflict on other members of the family and workplace, as well as how work – family conflict is influenced by broader contexts, such as the workplace structure and neighborhood of residence. Advancements in work – family scholarship may be made by exploring these areas of research further.

Family as Institution

Linda J Waite, University of Chicago, Chicago, IL, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The family is a mode of social organization often characterized by marriage and children. Permanence, joint production, coresidence, and the social recognition of a sexual and child rearing union are, perhaps, the most important characteristics of the institution of marriage. Although most children are born to married couples, increasingly childbearing occurs outside of the structure of marriage. The definition of family has changed to include nontraditional structures such as gay and lesbian partnerships, cohabiting couples, and nonmarried childbearing. In the United States, the share of adults who are unmarried has risen as more people delay first marriage and fewer remarry following the divorce from or the death of their spouse. The structure of the family differs around the globe, but remains one of the key social institutions in every society.

Family Mode of Social Organization

The family is "a social network, not necessarily localized, that is based on culturally recognized biological and marital relationships" (Thornton and Fricke, 1989). For the most part, this is still true. However, the rise of alternative family structures, including single parents, gay and lesbian partnerships, and cohabiting couples, sometimes including children, raises the question of whether a family must have a culturally recognized biological or marital relationship. In most cultures, a cohabiting couple living with their own child would constitute a family. But what of a woman, her child, and her cohabiting boyfriend? Does the family consist of the woman and the child, or does it include the boyfriend who has no marital, legal, or biological relationship to either one but lives with them and shares resources?

In most times and places, families were responsible for the production, distribution, and consumption of commodities; for reproduction and socialization of the next generation; and for coresidence and transmission of property. In many ways, the economic role of the family has remained unchanged. However, production of commodities and household specialization plays a decreasingly important role, due to increased longevity and declining fertility (which correspond to the fact that most of one's adult life is spent living in a household without one's own children) and increased rates of female labor outside of the home (Stevenson and Wolfers, 2007).

In most industrialized societies, the structure of the family looks quite different than it did a half-century ago. Fewer people live in families as traditionally defined. Fewer people are married, and alternative family forms such as single parenthood, cohabitation, and same-sex unions are on the rise. Changes in family structures affect family members, especially dependent children and elderly relatives. The departure from traditional marital unions seems to also coincide with the decline in fertility rates. And lower fertility rates, in turn, alter family structures, reducing family size and the number of relatives – from siblings to cousins to aunts and uncles and grandchildren – that people have.

Marriage

Permanence, joint production, coresidence, and the social recognition of a sexual and child rearing union are, perhaps, the most important characteristics of the institution of marriage. When two adults make a legally binding promise to live and work together for their joint well-being, and to do so, ideally, for the rest of their lives, they tend to specialize, dividing between them the labor required to maintain the family. This specialization allows married men and women to produce more than they would if they did not specialize. The coresidence and resource sharing of married couples create substantial economies of scale; at any standard of living, it costs much less for people to live together than it would if they lived separately. The economies of scale and the specialization of spouses both tend to increase the economic well-being of family members living together.

To put it another way, the sharing of economic and social resources through the institution of marriage acts as a sort of risk-spreader. Spouses act as a small insurance pool against life's uncertainties, reducing their need to protect themselves against unexpected events. Marriage also connects spouses and family members to a larger network of help, support, and obligation through their extended families, friends, and others. The insurance function of marriage increases the economic well-being of family members, and the support function of marriage improves their emotional well-being.

The institution of marriage also builds on and fosters *trust.* Since spouses share social and economic resources and expect to do so over the long term, both gain when the family unit gains. This reduces the need for family members to devote scarce resources to making sure that others in the family are acting in the family's best interests, thus increasing efficiency.

Marriage changes the behavior of spouses and thereby their well-being. The specialization, economies of scale, and insurance functions of marriage all increase the economic well-being of family members, and the increase is typically quite substantial. Generally, married people produce more of the goods and services consumed in the home and accumulate more assets than unmarried people (Lupton and Smith, 2003). Married people also tend to have better physical and emotional health than single people, at least in part because they are married (Mirowsky and Ross, 1989; Waite and Gallagher, 2000). The social support provided by a spouse, combined with the economic resources produced by the marriage, facilitate both the production and the maintenance of health.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32057-8

In most societies, marriage circumscribes a large majority of sexual relationships. Data from the United States show that almost all married men and women are sexually active and almost all have only one sex partner – their spouse. Unmarried men and women have much lower levels of sexual activity than the married, in part because a substantial minority have no sex partner at all (just under a quarter of the unmarried men and a third of the unmarried women who were not cohabiting had no sex partner in the previous year). Men and women who are cohabiting are at least as sexually active as those who are married, but are less likely to be sexually exclusive.

Married people and those in formally recognized cohabitations such as those in the Nordic countries (Kiernan, 2000) have higher fertility rates than unmarried and unpartnered. Indeed, a key function of marriage is the bearing and raising of children. In addition, children in married couples are better off, on average, on many dimensions than other children. A plausible explanation is that the institution of marriage directs the resources of the spouses and their extended families toward the couple's children, increasing child well-being.

Finally, marriage differs from other, less formal relationships primarily in its legal status. As previously mentioned, marriage is a legally binding contract. Spouses acquire rights and responsibilities with marriage, enforceable through both the legal systems and through social expectations and social pressure. As such, the treatment of marriage in the law shapes the institution and the extent to which it ensures family stability. Legally recognized cohabitations such as those in the Nordic countries share many of the same benefits (Kiernan, 2004).

Social and cultural traditions affect what constitutes a marriage and who is permitted to marry, and the degree to which marriage is considered a financial contract or a romantic one differs by region, religion, and culture. For example, consanguinity rates remain quite high in Sudan, Libya, and Saudi Arabia, where 40–50% of ever-married women ages 15–49 are wed to their first cousins (Rashad et al., 2005). On the other hand, some trends, like increasing age at marriage, pertain to nearly every region.

The Increase in Age at Marriage

Both men and women in the United States and many European countries are now marrying later than at any other time in at least the last 50 years. In the United States between 1970 and 2010, the median age of first marriage for American women increased by almost 6 years, from 20.8 to 26.7, and for men the median age increased by more than 5 years, from 23.2 to 28.7 (U.S. Census Bureau, 2010). From 1970 to 2000, the proportion of women who had never been married increased from 36 to 73% among those 20–24 years old and from 6 to 22% among those 30–34 years old. Similar increases occurred for men.

For African Americans, the delay in first marriage has been especially striking. The median age at first marriage increased to 30.8 for African American men and 30.3 for African American women (U.S. Census Bureau, 2011, Families and Living Arrangements). This represents an 8-year delay for African American men and a 10-year delay for African American women since the 1960s. And, in 2010, 47% of African American women and 50% of African American men ages 15 and older had never married (U.S. Census Bureau, 2010). Among families with black householders, only 44.4% were married couples compared with 80.8% of white family households (U.S. Census Bureau, 2011, Families and Living Arrangements).

Similar changes in marriage patterns have taken place in most European countries; recent cohorts are marrying at older ages and over a wider range of ages than in the past. Notably, European countries differ substantially in marriage ages. The Nordic countries of Sweden, Denmark, and Iceland show the highest average ages at marriage for women (around age 32). The Eastern European countries of Moldova, Ukraine, and Belarus show the lowest (around age 24) (UNECE, 2012, Statistical Database). The age at first marriage has risen substantially in Mediterranean countries over the last several decades. The mean age for first marriage for women was 22.3 in Greece, 24.1 in Italy, and 23.9 in Spain in 1980. In 2008, the ages increased to 28.9 in Greece, 29.9 in Italy, and 30.2 in Spain.

Delays in first marriage appear to have taken place in nearly every region on the globe, including the Middle East. For example, in the early 1970s, around 40% of women ages 15–19 were married in Kuwait and Libya, but these figures had dropped by the mid-1990s to 5 and 1%, respectively (Rashad et al., 2005). In Japan, woman's age at first marriage increased from 25.3 in 1987 to 27.4 in 2005 (Kaneko et al., 2008). The countries with the lowest age (between 17 and 18) at first marriage for women are Mali and Niger (United Nations, 2009b, World Marriage Data 2008).

The Decline of Marriage

Age at marriage has risen substantially, divorce rates are high and stable, and rates of remarriage have fallen, so that a larger proportion of adults are unmarried now than in the past. In 1970, unmarried people in the United States made up 28% of the adult population. In 2010, 44% of all adults were unmarried. In fact, the shift away from marriage has been so dramatic for blacks that in 2000, only 39% of black men and 31% of black women were married, compared to 59% of white men and 56% of white women (Fields and Casper, 2003). The decline of marriage has been largest among women with little education and almost nonexistent among college graduates, creating a divide in the family building experience along lines of class as well as race.

Though marriage rates have declined in the United States and other developed countries, the vast majority of adults do marry at some time in their lives. In the United States, more than 95% of men and women marry by age 50. And 75% of women who divorce remarry within 10 years. Relatively high proportions of men and women have not married by their late 40s in the Nordic countries where cohabitation is common (Kiernan, 2004). Caribbean countries such as Jamaica and Barbados, countries characterized by a long history of visiting relationships, in which couples are sexually active but live separately, show even higher rates of never married adults. In Sweden, for example, 24% of men and 16% of women in their late 40s had never married, and in Jamaica, 48% of men and

46% of women had never married by these ages. Delayed and foregone marriage appear to contribute to declining fertility trends, even as children (and childbearing) feature prominently in alternative family forms.

Cohabiting Families

Many contemporary heterosexual couples begin their lives together not in a marriage, but when they begin sharing a residence. They form intimate unions by cohabiting, with marriage usually following at some later point unless the relationship dissolves. In the United States, unmarried heterosexual cohabitation has become so common that most young adult Americans cohabit at some point in their lives. Rates of women cohabiting before age 25 have climbed from 7% of those born in the late 1940s to 55% among those born in the late 1960s. According to a recent estimate, 46.6% of American women between ages 15 and 45 will cohabit at some time in their lives (Heuveline and Timberlake, 2004).

Yet cohabitations tend to be relatively short-lived in the United States, with most either transformed into marriages or dissolved within a few years. The most recent estimates for the United States suggest that about 55% of cohabiting couples marry and 40% end their relationship within 5 years of moving in together. Only about one-sixth of cohabiting couples remain together without marrying for at least 3 years, and only 1 in 10 last for 5 years or more without either splitting up or marrying (Bumpass and Lu, 2000). As a result, the proportion currently cohabiting is only about 10% among women ages 20–29, compared to 27–53% currently married at these ages, respectively. At older and younger ages, fewer than 1 woman in 10 is currently cohabiting.

In the United States, cohabitation has become an increasingly common step in the courtship process, preceding the majority of marriages and remarriages. The percentage of marriages preceded by cohabitation increased from about 10% for those marrying between 1965 and 1974 to more than 50% of those marrying between 1990 and 1994. And cohabitation is especially common for those whose first marriage dissolved.

Although a number of European countries have experienced similar increases in cohabitation, some have experienced much more and some much less (Kiernan, 2004). Cohabitation is strikingly common in the Nordic countries of Denmark, Sweden, and Finland; France also shows fairly high levels, with over 30% of the women and men ages 25–34 in cohabiting unions. By contrast, a group of countries including the Netherlands, Great Britain, Germany, and Austria shows moderate levels of cohabitation, with 15–22% of women from ages 20 to 34 are in this type of union. And in the Southern European countries of Italy, Greece, and Portugal, cohabitation is rare, with less than 10% cohabiting among women in this same age group (Kiernan, 2004).

In some countries, cohabitation is a socially recognized form of partnership that is quite stable and seems to function more as a permanent alternative to marriage rather than a substitute for it. Sweden, France, and Canada fall into this category. In other countries, such as Belgium, Austria, and Germany, cohabitation appears to be more like a prelude to marriage or a stage in the courtship process. By contrast, cohabitation appears to be relatively rare in Italy, Poland, and Spain. In Latin America and the Caribbean, a significant number of girls aged 15–19 elect to live in consensual unions, with rates of almost 24% in Brazil, 20% in Nicaragua, and 18% in Dominican Republic (United Nations, 2009a, Demographic Yearbook data collections).

Cohabiting couples share a residence and a sex life, but they need to share little else. At least in the United States, cohabiting couples are much less likely than married couples to combine financial resources, less likely to be sexually exclusive, less likely to share leisure time and a social life, less likely to have children, and less likely to remain together. The requirements for establishing or ending a cohabiting union are minimal, with no legal or religious or community formalities involved. Thus, some scholars argue that cohabitation and marriage are distinct social institutions. According to some scholars, cohabitation is much less institutionalized than marriage, at least in the United States and other countries in which it has become common relatively recently, because it is not covered by clear expectations or norms, and the legal rights and responsibilities of cohabiting partners have not been established (Waite and Gallagher, 2000).

So while many people choose cohabitation over marriage, a number of conditions will need to be met before cohabitation becomes indistinguishable from marriage. Cohabitation will provide a comprehensive substitute for marriage only when couples tend to select either cohabitation or marriage at the beginning of their relationship and rarely make the transition from cohabitation to marriage; when cohabitations become about as stable as marriages; when cohabiting couples become socially recognized as permanent unions and treated as married; and when childbearing takes place in cohabiting relationships at about the same rate as in marriage.

Although not all of the above conditions apply, the gap between marriage and cohabitation is narrowing in some countries, such as in the Nordic countries, where cohabitation has much the same legal and social status as marriage. But even in the Nordic countries, cohabiting relationships are less stable than marriages, with at least one in five of the unions dissolving before the child reaches the age of 5 if the cohabitation does not lead to marriage (Kiernan, 2004).

Unmarried Childbearing

Changes in marriage have played a central role in increases in unmarried childbearing, which has reached historically unprecedented levels (Bachrach, 1998); in 2010, 41% of all births and 44% of all first births in the United States occurred to women who were not married (Martin et al., 2011). The proportion of births to unmarried women has increased without interruption from 1997 through 2009. This level compares with 33.2% in 2000 and 18.4% in 1980. Contrary to public perception, teenagers under age 20 accounted for just 21% of all nonmarital births in 2009, down from 29% a decade earlier (Martin et al., 2011). In fact, births to unmarried women increasingly occur in cohabiting households. According to the National Center for Health Statistics based on data collected from 2006 through 2010, the percentage of first births to women living with a male partner jumped from 12% in 2002

to 22% in 2006–10 – an 83% increase. Likewise, the percentage of cohabiting new fathers rose from 18 to 25%. In some regions of the United States, these numbers are even more striking. In an analysis that surveyed 250 families with unmarried parents in Oakland, California, and tracked the parents' relationships for 1 year from the time of their child's birth, half of the parents were living together when their child was born (Waller, 2001).

The proportion of births to unmarried women depends on the share of all women who are married, the fertility of married women, and the fertility of unmarried women. Marital fertility is relatively low in the United States and many European countries. Where nonmarital fertility is also low, as it is in Spain, Italy, and Japan, total fertility is substantially below replacement, but those low-fertility countries with fairly high levels of nonmarital childbearing, like the United States and France, tend to have higher total fertility (Rindfuss et al., 2000).

Unmarried childbearing varies substantially among racial and ethnic groups in the United States. The percentage of births to unmarried women is highest for black women (73%), and lowest for Asian and Pacific Islander Americans (17%), with Hispanic women (53%) and non-Hispanic whites intermediate between these two extremes at 29% (Martin et al., 2011). Unmarried childbearing also varies considerably across states and regions, but these differences can primarily be attributed to the racial compositions of these areas.

As we might expect from differences in the proportion of women who are single and in the proportion in cohabitational unions, unmarried childbearing also varies dramatically across countries in Europe. The Nordic countries, which have a high rates of cohabitation, also have quite high percentages of births to unmarried women; in Norway, for example, 46% of births in recent years occurred to unmarried women, most of whom were cohabiting. More than half of births in Sweden and almost half in Norway occur to unmarried women. In 1980, Mediterranean countries saw rates of birth to unmarried women under 5%; in the last several decades, these percentages have more than quadrupled, with 28% of births in Spain and 21% in Italy to unmarried mothers (Ventura, 2009). The social implications of unmarried childbearing depend on both the extent to which these births take place within stable, socially recognized cohabiting couples, like in the Nordic countries, and the extent to which social welfare programs cushion the financial impact on the family of having a single parent. Where few supports for single parents exist, like in the United States, children in these families do less well than children raised in two-parent families, but even under these circumstances, most children raised by single parents are happy and successful as adults (Amato and Booth, 1997).

Alternative Family Forms

The married, two-parent family has historically been the most common family form in the United States and other industrialized countries for some centuries. However, as just discussed, the proportion of women who are married has declined substantially over the last half-century in developed countries. At the same time, the proportion of U.S. families consisting of a married couple with children fell from 43% in 1950 to 20% in 2010 (Frey, 2010). Even at the height of the married-couple family era, many people lived in other types of families, most often due to the death of one member of the couple before all the children were grown. When death ended many marriages relatively early in life, remarriage and stepfamilies were common, as were single-parent families caused by widowhood (Watkins et al., 1987).

High rates of divorce combined with relatively low rates of remarriage, especially for women with children, have led to sizable proportions of families headed by a divorced single mother. In addition, the rise of cohabitation and nonmarital childbearing, discussed in detail previously, has meant that unmarried-couple families and never-married mother families are now common alternative family forms. 'Nonfamily' households are also on the rise; these consist of a person living alone or with nonrelatives only, such as roommates or an unmarried partner. In addition to delayed marriage, nonmarriage, continued high rates of marital disruption, and lower rates of remarriage, the rise in nonfamily living can also be traced to earlier nest-leaving by young adults and to increases in independent living at older ages. In 2010, 34% of all households did not contain a family compared to 19% in 1970. And people living alone formed 27% of households in 2010, up from 17% in 1970 (U.S. Bureau of Census).

Gay and Lesbian Families

One alternative family form consists of two adults of the same sex, sometimes raising children. Historically and traditionally, a family consisted of people related by blood or marriage in a culturally recognized social network of biological and marital relationships. In many places, marriage continues to be defined as a legal relationship between an adult man and an adult woman who form a new family. Gay and lesbian families, sometimes based on a socially recognized and sometimes on a legally recognized relationship, challenge these definitions. Attitudes toward sex between two adults of the same sex have become substantially more accepting in the United States over the past several decades, with about half of Americans agreeing that homosexuality should be accepted by society (Wike and Menasce Horowitz, 2007, Pew Research Center). At the same time, extension of the definition of family and marriage to same-sex couples has been hotly contested and fiercely debated.

In the United States, many attempts to extend access to marriage and family rights to same-sex couples have been turned back by legislators or voters, with some notable exceptions. Same-sex marriage has become legal in six states: Connecticut, Iowa, Massachusetts, New Hampshire, New York, and Vermont. Washington, D.C. and two Native American Tribal jurisdictions (Coquille and Suquamish) perform same-sex marriages as well. Maryland and Rhode Island recognize same-sex marriages from other states. Still, 9 states prohibit same-sex marriage in statute and 30 prohibit it in their constitution. Several European countries have moved furthest on these issues. For example, France allows same-sex couples to register their partnerships as civil unions; Denmark has extended child custody rights to same-sex couples; and perhaps most definitively, the Netherlands became the first country to grant same-sex couples full and equal rights to marriage in 2000. Since then, 10 countries (Argentina, Belgium, Canada, Denmark, Iceland,

Norway, Portugal, Spain, South Africa, and Sweden) and parts of Mexico have begun to allow same-sex couples to marry.

The National Survey of Family Growth reported that 3.4% of women and 3.6% of men identify as gay, lesbian, or bisexual, based on data from 2006–08 (Chandra et al., 2011). However, it can be incredibly difficult to ascertain rates of homosexuality due to the fact that people respond based on identity, activity, and attraction. For example, in the National Survey of Family Growth, 11% of adults reported attraction to members of the same sex and 8.8% reported same-sex behavior, but only 3.7% of adults identify as lesbian, gay, or bisexual (Chandra et al., 2011). Additionally, in the United States, more people typically identify as bisexual, especially women, than in other international studies. According to revised estimates from the 2010 Census, there were 131 729 same-sex married couple households and 514 735 same-sex unmarried partner households in the United States, roughly 0.56% of U.S. households (U.S. Census Bureau, 2010). This census is the first to collect data on same-sex married couple households.

Single Adults and Single Parents

Given that many couples in the United States and similar countries begin their intimate lives together by cohabiting rather than by marrying, it seems that the form of the union has changed more than its existence. But even when we consider both marriage and cohabitation, young adults are less likely to have formed a union now than in the past. Among young women born in the early 1950s, about one-quarter had not formed a union by age 25, compared to one-third of those born in the late 1960s. More adults are remaining single longer.

In many European countries, women typically are in either cohabiting or marital unions by their mid- to late 20s. However, 55% of Italian women and 41% of Spanish women have never been in a partnership – neither cohabited nor married at these ages, compared to around one in three Portuguese and Greek women. In the Nordic countries and France, about one-third of women ages 25–34 are single, one-third are cohabiting, and one-third are married. Union dissolution contributes to the numbers of single men and women, as does postponement of union formation, cohabitation, and marriage (Kiernan, 2004).

A number of large-scale social changes are implicated in the postponement and decline in marriage and the increase in cohabitation, divorce, and unmarried childbearing. These include the development of effective contraceptives, especially the birth control pill, and legalization of abortion, both of which contributed to the sexual revolution. These changes lowered the costs of sex between unmarried partners at the same time that attitudes toward sex between unmarried people liberalized dramatically. The sexual revolution also lowered the costs of delaying marriage, since one could have an active sex life while single, and gave women and couples much more control over the occurrence and timing of births. This latter change dovetailed neatly with women's increasing labor force participation, which was, in turn, both facilitated by and a consequence of rises in women's investment in their own education (Goldin and Katz, 2002).

Sex

In spite of the sexual revolution, marriage circumscribes the vast majority of sexual relationships. Almost all married men and women are sexually active and almost all have only one sex partner – their spouse. Unmarried men and women have much lower levels of sexual activity than the married, and frequently have no sex partner at all. Cohabiting couples are at least as sexually active as married couples, but are much less likely to be sexually exclusive (Laumann et al., 1994). Thus, the married couple remains the locus of the vast majority of sexual activity.

Social and cultural attitudes structure sex and partnership throughout the life course. For example, Latina adolescents tend to engage in sexual activity with partners who are 'substantially older' (four or more years) at much greater levels than other adolescent girls (Martinez et al., 2011). African American adolescents are more likely than other teen populations to have stronger attachment to their families than their friends, perhaps explaining why African American youth tend to have longer lasting but less intimate romantic relationship styles than other youth (Smetana and Gettman, 2006). Differences in culture, religion, and socialization remain important influences of sexual partnerships throughout the life course.

Physical health and sexual function structure sex and partnership patterns as well. Sexual attitudes and experiences change over the life course for men and women. Patterns in the availability of a partner over the life course are gender differentiated, primarily due to women's greater longevity and likelihood that they are married to men older than themselves. Men's likelihood of being in a marital or cohabiting relationship remains over 80% and stable into their 60s. Among women, however, partnership prevalence drops sharply after the early 50s (Waite et al., 2009).

Conclusions

Many public commentators and some scholars of the family argue that the family is under siege from legal, economic, and social change and in decline as a result (Popenoe, 1993). As evidence, they point to low marriage rates, high divorce rates, and low marital and high nonmarital fertility. And this evidence is compelling, as far as it goes. But most adults are married (although it is a remarriage for many), most have children, most rate their marriage as very happy and place a high value on family life, and most have only one sex partner – their spouse. Most single parents raise happy and successful children. This evidence suggests that the family remains a key social institution, even in its altered state.

Family Business

Guido Corbetta, Bocconi University, Milan, Italy

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Family business is an interdisciplinary field devoted to study the structural and transitional problems of family firms. Family firms can be defined as companies of various sizes controlled by one or more owners tied by family relationship or solid alliances. The recent important theoretical and empirical developments have crystallized a double-edged vision of the family firm, which includes both the positives and the negatives of family control descending. Future studies should propose research designs that take into account the need to go beyond simple – although powerful – variables such as family ownership and leadership. As in most of the managerial fields, the simultaneous search for rigor and relevance should dominate the scholarly agenda over the next few years.

Family business is an interdisciplinary field, born as an autonomous one only in the early 1980s, involving all professionals who advise, study, and work in family firms addressing their structural and transitional problems. Family firms are dynamic systems including two subsets, the family and the firm. Traditionally, family firms have been considered as a residual of the past that inhibits the development of more efficient 'managerial' firms with dispersed shareholding. However, different factors have persuaded individuals and institutions to work on them in research and practice: high and persisting relevance in modern economies, evidence that family firms are able to grow up to very large sizes, and the need to support them to overcome the difficulties to go beyond the first generation. Today, there are 57 endowed Chairs in Family Business mostly in the United States and Europe.

Family firms can be defined as companies of various sizes controlled by one or more owners tied by family relationship or solid alliances (see Corbetta and Salvato, 2012). Despite this general tenet, there are different possible definitions of the family firm. Westhead and Cowling (1998), for instance, were among the first to notice how previous research relied on alternative views about what the family firm is. Such definitions were based on (1) the entrepreneur perception of being a family firm, (2) the family ownership, (3) the family management, and (4) the intergenerational ownership transition (Westhead and Cowling, 1998). Chua et al. (1999) noticed how different researchers use varying definitions of family involvement (in the ownership, in the business, or both) to qualify a family firm, and hence proposed an alternative theoretical definition based on the differential characteristics of family firms vis-à-vis the others. More precisely, they define the family firm as "a business governed and/or managed with the intention to shape and pursue the vision of the business held by a dominant coalition controlled by members of the same family or a small number of families in a manner that is potentially sustainable across generations of the family or families" (Chua et al., 1999: 25). The same scholars in a later study further enucleate the four distinguishing points of the family business definition, which are (1) the intention to maintain family control by the dominant coalition, (2) a set of resources and capabilities arising from family involvement and interactions among family actors, (3) a vision set by the family controlling the firm, and (4) the pursuance of such vision. Along the same line, Astrachan et al. (2002) proposed an index of family involvement called Family-Power, Experience, and Culture (F-PEC), which enables the assessment of family influence on a continuous scale rather than restrict its use to categorical variables (yes/no), and allows comparisons across businesses concerning levels of family involvement, and its effects on performance as well as other business behaviors.

While most of the empirical research refers to family ownership, ownership-based definitions adopted in different studies are largely dependent upon size and other firm characteristics, as well as upon the institutional context. For instance, while Anderson and Reeb (2004) in their study of large US firms used family control thresholds ranging from 5 to 10%, other studies relied on a considerably larger threshold of 50% of shares for private, reduced to 30 or 25% for listed firms (e.g., Minichilli et al., 2010).

The relevance of family business has recently been recognized also by important institutions such as the European Commission, which set a Family Business Group to discuss and research on family firms in individual countries, and the critical issues they face. One of the most important outcomes of the activity of this group has been to come up with a definition, included in the 2009 Report of the EU Commission. According to this definition, "A firm, of any size, is a family enterprise if: 1. The majority of votes is in possession of the natural person(s) who established the firm, or in possession of the natural person(s) who has/have acquired the share capital of the firm, or in possession of their spouses, parents, child, or children's direct heirs. 2. The majority of votes may be indirect or direct. 3. At least one representative of the family or kin is involved in the management or administration of the firm." This definition also applies to listed companies that meet the definition of family enterprise if the person(s) who established or acquired the firm (share capital) or their families or descendants possess 25% of the right to vote mandated by their share capital (EU Commission, Report, 2009). This was the first time that an official, high-level body adopted a definition of the family firm in order to establish a framework for successive

policies to promote the development of these companies. We can take this as a clear sign of the prominent position of family firms, at least in the European context.

Origins and Development of Family Business Field

Even if some family business articles appeared in the 1950s, 1960s, and 1970s, only at the beginning of the 1980s was family business born as a field acknowledged by a number of North American scholars and practitioners. A fundamental contribution was made by a management researcher (Richard Beckhard, Management and Organization Behavior Professor at MIT Sloan School of Management for more than 20 years), by a psychology researcher (Harry Levinson, professor at the Psychiatry Department at Harvard Medical School), and by a consultant (Léon Danco, CEO of the Center for Family Business in Cleveland). In the mid-1990s, they have been recognized publicly as family business pioneers and interviewed in the 1994 *Family Business Review* (FBR) issue (vol. 2) dedicated to the field's history; in these interviews, they all admit to how difficult it was to make the scientific community accept the existence of family business as a special discipline.

The first studies in family business were case descriptions without any interpretative framework, which made it difficult to open a scientific debate. Most family business professionals were practitioners at that time; as such, they were not well respected as researchers by the scientific community. Further, they were not very committed to publishing in order to share their knowledge and experiences with others.

Generally speaking, family firms traditionally have been considered – and not only by academics – as a residual of the past to overcome, beginning from the study by Berle and Means (1932) who considered separation between ownership and control as a fundamental condition of development for modern economies. Not surprisingly, the media were used to dealing with family businesses only to highlight how disputes among family owners or nepotistic behaviors negatively impacted the business.

In 1984, something of decisive importance in the development of family business occurred: a group of North American scholars and practitioners, coordinated by Barbara Hollander, gave rise to the Family Firm Institute (FFI). By means of its various services, FFI has become a special forum for knowledge sharing and development. Particularly, annual conferences and the FBR – founded by Ivan Lansberg in 1988 – have been fundamental tools that helped develop theory and practice. In the leading article of the first issue, Lansberg himself provided significant data about how early the stage of the field's development was: according to a study conducted on the Social Science Citation Index from 1977 to 1987, only 53 articles had been published in the United States on family business issues, as compared with the 813 on entrepreneurship.

In 1990, the Family Business Network (FBN) was founded in Europe. Despite its different membership policies (there are more family business members and less professionals), FBN fulfills a similar mission by spreading family business knowledge and fostering a scientific and cultural debate on this topic.

The increasing number of monographic issues on family business published in such reviews as Organizational Dynamics (summer 1983), Business History (October 1993), and Entrepreneurship Theory and Practice (1 November 1994) shows that rising attention has been devoted to this new discipline by scholars in other fields as well.

In the United States and in other parts of the world, some universities followed the increasing interest on the part of scholars and other stakeholders toward family business.

Different factors have persuaded individuals and institutions to growingly invest resources in exploring family business. Among these is the diffusion of data about the importance of family businesses in modern economies, evidence that family firms can grow big and cannot just be identified with small and medium enterprises (SMEs), and consciousness of the difficulties for family firms to last beyond the first generation. Last but not least, empirical evidence suggests that family firms represent the most common type of organization around the world. Although the different national figures vary according to the operational definition being used, family firms account for (1) 80–90% of all business enterprises in the United States, with a remarkable presence of those firms also in very large businesses (about one-third of the Fortune 500 firms are family controlled, with this number rising up to 50% for the Fortune 1000 firms); (2) more than two-thirds of firms in Australia, and the majority of businesses in the United Kingdom; (3) the vast majority of companies in most of the European Countries, for example, 83% in France, 82% in Italy, and 79% in Germany; and (4) around 95% of all firms in Asia and the Middle East, as well as the majority in other emerging countries such as Brazil (FFI global data points; Gomez-Mejia et al., 2011). This widespread presence secures an estimated percentage of the global annual gross domestic product ranging from 70 to even 90%, employing the majority of the active workforce in most of the industrialized countries in the world (FFI global data points).

Research Areas and Achieved Results

The first family business studies mostly concerned founder succession issues, which is either transition from the controlling owner archetype to another or recycling of the same archetype with different actors. Such studies (1) considered small- and medium-sized firms with simple managerial structures, which typically dealt with simpler family situations; (2) focused on leadership transitions from the founder to the heir, without an explicit acknowledgment of other family and business members, and often overlooking the importance of ownership changes; (3) considered the family as an obstacle to the effective and efficient management of the firm, suggesting a sharp distinction between family and enterprise as a fundamental condition for the business continuity.

Even if most of these studies, heavily rooted in a rationalistic approach, have been revisited or have even become outdated, they achieved the important result of opening up a new research stream by explicitly recognizing the differences – in terms of roles, goals, and needs – and the mutual influence between the family and the business.

However, the growth of the family business field occurred mostly in the past 20 years, with several important conceptual

and empirical developments that can be summarized as follows:

1. The definition of the main dynamic relationships between family and business using interpretative frameworks based on different stages of the firms, people, and families' life cycles. Along this line, Miller and Le Breton-Miller (2005) identified four elements that should secure the family businesses' success in the long run. They are (1) continuity, that is, the will of family firms to constantly and passionately realize their mission; (2) community, achieved through a cohesive team of employees united by strong values; (3) connections, since relationships with partners vastly exceed the time span and scope of ordinary market transactions; and (4) command, since family business decision makers are able to act independently, rapidly, and without rigid restrictions from shareholders;
2. A more in-depth (and insightful) approach to family business successions, admitting complex situations characterized by multiple family and nonfamily leadership candidates, and subsequently stating the importance to base the successor's selection on specific criteria such as motivation, managerial abilities, career development, outside work experience, formal education, training programs, etc.;
3. A closer attention to the differences between different types of family firms, going beyond the traditional overlap with small- and medium-sized enterprises. Along this line, Corbetta proposed four archetypes of family firms corresponding to different sizes and ownership concentration levels, and also showing typical evolutional patterns from one stage to another. Consistent to this, recent studies are increasingly arguing for the importance of sampling issues, both in terms of firm size and family ownership concentration, to influence actual research results (e.g., Miller, 2013);
4. A theoretical and empirical quest to understand the direct family ownership effects on firm behavior and performance, leading to conceptualize both the negative sides due to increasing agency costs related to problems of altruism and self-control (Schulze et al., 2001), as well as the positive sides of 'distinctive familiness,' which can lead to family-based advantages and transgenerational wealth creation (Habbershon et al., 2003). Despite the long-lasting search, however, a recent large-scale meta-analysis showed that on average family ownership has either no effect or at best offers a small performance advantage relative to other types of ownership.
5. A stronger focus on formal aspects of family governance and leadership, including the functioning of boards of directors (Anderson and Reeb, 2004), but mostly the effect of family leadership on firm performance (Anderson and Reeb, 2004; Minichilli et al., 2010). While most of these studies report a positive effect of family leadership, others raise the importance to contextualize these results within specific family firm 'types' or 'configurations' (Miller et al., 2013).
6. The importance of recognizing different levels of analysis in family business research, going beyond the importance of individuals and individual leaders, but also considering (1) interpersonal or group-level relations (e.g., between different groups of family and nonfamily employees and managers); (2) organizational level, pointing out five different sources of capital such as human, social, survivability, patient capital, and family governance structures; and (3) the role of family firms in society and at a societal level (Sharma, 2004);
7. The distinctive behavior of family firms, with respect to emotions, exploring various constructs such as emotional capital, emotional ownership, emotional returns and costs, and emotional value. These ideas have been recently conceptualized in the socioemotional wealth (SEW) approach in studying family business (Gomez-Mejia et al., 2011);
8. The influence of emotions and distinctive family (economic and noneconomic) goals on strategic objectives and decisions in family firms. According to Chrisman et al. (2005), family firms show relevant specificities in terms of (1) strategic objectives, which go beyond profit maximization and include set nonfinancial goals such as family satisfaction and sustainability of the business across the family's lifetime; (2) strategic choices, which include also quality and long-term relationships with suppliers, customers, and local communities; and (3) strategic processes, which tend to be based on trust mechanisms, cohesion, and a value-driven business orientation made possible by higher levels of goal alignment between owners and managers;
9. The subsequent strategic alternatives available to family firms, providing insights on the business or corporate strategies used by family firms to exploit their unique resources and capabilities. As such, various studies considered the relationship between family involvement in the business and choices such as diversification, acquisitions, corporate social responsibility, and financing choices, among others.

These important theoretical and empirical developments have crystallized a double-edged vision of the family firm, which includes both the positives and the negatives of family control descending from the previous considerations, also characterized as the 'bright' and the 'dark' side of family involvement in business (Minichilli et al., 2010). According to a recent review, the positive aspects include (Gomez-Mejia et al., 2011) the following:

- Patient capital that values long-term returns over short-term gains;
- Affective commitment of owners, managers, and employees;
- A culture that fosters employee identification with the organization and lower employee turnover, thereby ensuring continuity and the capacity to pursue long-term projects;
- Accumulation of social capital, which becomes a 'moral resource';
- Continuity of leadership, offering greater resilience in hard times and faster decision making.

These aspects turn into negative aspects of the family when one (or more) of the following phenomena occur (Gomez-Mejia et al., 2011):

- Appropriation of firm resources to satisfy parochial family desires;

- Nepotism, cronyism, and incompetent family members on the payroll;
- Excessive effort expended on family emotions and conflict, which distract from paying attention to market forces and business matters;
- The 'spoiled kid syndrome,' which can create feelings of inequity among employees;
- Parental altruism, overuse of business perks, and biased hiring decisions.

The intellectual curiosity to further explore the pros and cons of family involvement in business in different types of firms, as well as in different contexts, resulted in a growing number and quality of scientific articles both in field and in top-tier generalist journals. This is witnessed by the impact factor (IF) trend of the field journal (FBR), which obtained the first IF in 2007 (equal to 0.67), growing up to 2.42 in 2010, at comparable levels of more established management journals. At the same time, the interest in the topic has been marked by a wealth of articles published in journal special issues. Among the most recent experiences, Schulze and Gedajlovic edited in 2010 a special issue for the *Journal of Management Studies* entitled 'The family and enterprise: Unpacking the connections,' and exploring a number of emerging issues in family business research such as the impact of top management teams' composition and diversity on performance, the diversification decisions in family-controlled firms, or the effect of family control and ownership in different institutional settings. Interestingly, then, Steir, Lumpkin, and Wright edited in 2011 a further special issue in the *Strategic Entrepreneurship Journal* entitled 'Strategic Entrepreneurship in Family Business,' in which they discuss the ways in which the influence of family matters to strategic entrepreneurship, and how strategic entrepreneurship can contribute to understanding and strengthening of family firms, discussing concepts such as entrepreneurial orientation and portfolio entrepreneurship in family firms, mostly in a resource-based framework.

Finally, the interest in family business research has overcome in the past decade the boundaries of management research, with a growing number of contributions from influential scholars from the fields of economics, finance, and even sociology. Economists for the most part have tended to focus on questions relating to the governance of the family firm and its influence within the global economy (La Porta et al., 1999), focusing on the variety of mechanisms that family-controlled firms use to enhance their power, while finance-oriented scholars mostly concentrated attention on the role of family managers' style on firm performance, as well as the impact of family and nonfamily CEOs' succession (Bennedsen et al., 2007).

From the Present to the Future of Family Business Studies

The Theoretical Arena

A first important element to identify future directions of development for the field relates to the theoretical arena, which today characterizes family business studies. Despite the impressive number of published conceptual articles, indeed, it seems that family business scholars mostly used established theories, applying them to family firms for the purpose of understanding and explaining their uniqueness.

According to agency theory (Jensen and Meckling, 1976; Schulze et al., 2001), one of the common assumptions of economic-based investigations of family firms is that they are believed to lower agency costs due to the alignment of interests between owners and agents. Nevertheless, recent interpretations and substantive works by Bill Schulze and colleagues emphasized the negative aspects of close alignment between owners and agents, and highlighted the risk of the so-called parental altruism,' that is, the tendency of parents to attribute benefits to family members (e.g., higher compensation, consumption of perks, and generous or 'familial' appointments), in general, serving all the specific interests of the family.

The 'failure' of the agency theory to satisfactorily explain the family executive's behaviors led scholars to rely more on psychological aspects of human beings to support evidences from family business studies, such as the stewardship theory (Corbetta and Salvato, 2004). According to the stewardship theory, in serving their corporations, family executives are driven by both economic and noneconomic rationales, and experience satisfaction from the ability to share, help, and support other cherished family members in the process. They are also motivated by a need to gain intrinsic satisfaction through effectively performing exigent work, and thereby to gain recognition from peers and superiors. This contributes to these managers' sense of identity and self-esteem deriving by identification with their company and their fulfillment of family obligations.

The growth in rigor, relevance, and width of family business studies over years progressively attracted attention from strategy scholars, with the natural consequence of cross-fertilization among studies and theories. One of the most notable results has been the rise of the resource-based view (RBV) (Barney, 1991) as a theoretical lens to identify resources and capabilities that are unique, scarce, valuable, hardly imitable, and with significant rent potentials within family firms. Under this view, family involvement (so-called familiness) contributes to the building up of competitive advantage over 'faceless' competitors for the firm through higher stocks of social capital and 'patient' financial resources that enhance the firm's economic sustainability and longevity (Miller and Le Breton-Miller, 2005). These resources can also contribute indirectly to firm performance through the achievement of outcomes such as the preservation of family ties and transgenerational value creation (Sharma, 2004).

Nevertheless, the inability of the agency, stewardship, and RBV to univocally predict the positive or negative side of family businesses led a number of scholars to propose novel interpretative theoretical lenses to investigate family business phenomena.

On the one hand, some studies tried to combine agency and stewardship predictions in order to reconcile predictions stemming from the economic and psychological rationales that characterize, respectively, those two theories. As a result, many other studies suggest that family involvement is an unambiguously positive or negative influence, whereas the interpretive framework proposed by these scholars significantly conditions both those expectations. The underlying thesis here is that both

these well-argued views of family business may hold, but under different circumstances, largely characterized by the degree to which a business and its top executives are embedded within a family.

On the other hand, another group of scholars tried to introduce a new paradigm in the family business field, which again combines psychological and economic rationales in family firms' decision making, but using the preservation of the 'socioemotional endowment' of a family as the economic reference point for strategic decisions. Introduced by Gomez-Mejia et al. (2011) as a variant of the behavioral agency model, the SEW perspective refers to nonfinancial aspects of the firm that meet the family's affective needs, such as identity, the ability to exercise family influence, and the perpetuation of the family dynasty. Based on the assumption that family firms may give priority to socioeconomic rather than purely economic rationales, the preservation of SEW is a crucial feature of family firms.

The SEW perspective has recently been used in the context of family firms to explain their uniqueness with regard to a range of topics, such as managerial entrenchment or executive compensation. The general conclusion from this research is that controlling family owners tend to be guided by a set of motives different from those for other types of owners.

Theory Building or Theory Testing: Rigor and Relevance

The theoretical prolificacy represents one of the distinctive features of the family business field, as well as one of its potentially problematic issues. Searching for a unique (and unifying) conceptual framework to understand family firms' characteristics and behavior, scholars have traditionally attempted to propose new concepts, ideas, and framework, with the result that empirical testing of newly elaborated constructs has been often downplayed. Among recent studies published in the FBR, for instance, constructs and related propositions on family emotions, family social capital, and knowledge integration have been proposed, but not tested yet. This evidence parallels calls from the SEW growing literature: despite SEW being so far used as an interpretative framework to explain outcome variables, few or no studies actually measured the socioemotional dimension of families, and the challenge to measure SEW is definitely next.

This impression is confirmed in a recent work (Tognazzo, 2012), which considers 279 articles published in the FBR from 1998 to 2010, for the purpose of distinguishing between theory building (introducing new constructs, new relationships, or variables) and theory testing (test hypothesis on the bases of previous theories using large samples). Interestingly, trends of theory building and testing in FBR are stable over the past decade, with theory building dominating over theory testing, exactly the opposite of what the author found in more traditional journals such as the *Academy of Management Journal*, *Administrative Science Quarterly*, and *Strategic Management Journal*, in which theory testing instead dominates. At the same time, however, the relevance for practice, which traditionally characterized FBR articles, significantly dropped in the past decade, with the article practical relevance score halved during the period considered for the analysis. It confirms a tendency toward a proliferation of new constructs and relationships, at the expense of more 'rigorous' tests of established paradigms on large samples, also in order to gain legitimacy in the field, as well as of 'relevant' research with practical implications. As in most of the managerial fields, the simultaneous search for rigor and relevance should dominate the scholarly agenda over the next few years.

Some Insights on the Next Developments in the Family Business Field

Drivers of Development

A recent survey of 80 family business scholars by Litz et al. (2012) about the state of the art and future developments of the field supports the above insights and considerations. Specifically, the authors contend how, although the field has achieved a substantial consensus, this consensus is at best of a penultimate nature (Litz et al., 2012). In other terms, the impressive growth experienced by the family business field in the past two decades has potential downsides that inhibit proper consensus. On the one hand, the fast rise in numbers of doctoral students and scholars interested in the topic determined a scattered growth characterized by spotty referencing and fragmented views of the field, casting doubts about whether this quantitative growth has always been accompanied by a qualitative development; consequently, while there is definite consensus that questions relating to family business are important, there is much less consensus as to the answers (Litz et al., 2012). This lack of consensus is mirrored by additional insights stemming from the survey. As the authors effectively summarize, "the field will need to develop and innovate by expanding its conceptual boundaries to mode deliberately include the family, enlarge its temporal boundaries to more reflectively appreciate the past, open its international boundaries to welcome findings from a growing array of international and ethnic contexts, and enrich its inherent complexity to appreciate works that present novel variables and engage in increasingly diverse set of topics" (Litz et al., 2012, p. 30).

In addition to consensus, a second important driver of development might be an increasing reliance on an interdisciplinary approach to the field. In terms of necessary competencies, many family business scholars believe that most research topics need interdisciplinary team effort; in particular, researchers in different branches of management, psychology, and sociology should cooperate to capture the distinctive facets of family business. For instance, organizational behavior and social psychology can help one to better understand the role of emotions in these firms, finance can contribute in helping one to understand the constraining role of capital and financial markets on future growth, and sociology can help one to unravel the influence of institutional pressures and family networks on firm survival (Gomez-Mejia et al., 2011). The reason why interdisciplinary collaboration is not well developed is most likely because of the high costs of joint research due to the very different starting points in terms of knowledge, languages, and methodologies. Nevertheless, since in many fields radical advances come from collaboration between authors in different disciplines and professions, such collaboration should be strongly encouraged.

Relevant Topics and Methodological Challenges

In terms of content, the future development of the field will be characterized by a number of relevant issues, as well as by important methodological challenges.

On the one hand, companies' strategic context is significantly changing because of the impact of new technologies and globalization, as well as the impact of the economic crisis that started in 2008. As such, the family businesses' capability to compete in such a context will represent a relevant research topic. Another key issue will be the impact of increasing managerial and financial sophistication on the culture and behavior of family businesses, as well as the responses of family firms to increasing institutionalization of their governance forms. This is evident in the recent development of codes of good governance for private firms (Buysse Code in Belgium; EcoDa Recommendations; Institute of Directors' Code in the United Kingdom), and specifically for family firms (IFC Family Business Governance Handbook – World Bank; Governance für Familienunternehmen in Switzerland; Guía Colombiana de Gobierno Corporativo para Sociedades Cerradas y de Familia in Colombia).

This is also related to what Chrisman et al. (2010) propose in their review and research agenda. According to these scholars, three important emerging issues in the family business research are (1) family governance systems, devoting more attention to monitoring mechanisms, informal family system versus formal ones, boards of directors in family enterprises, with the need to investigate further their composition, functioning, and performance; (2) owner–owner agency costs, investigating situations in which controlling owners may extract benefits from the firm at the expense of minority owners; and (3) noneconomic goals, which include how the pursuit of noneconomic goals can provide competitive advantage or, on the contrary, more conservative behaviors (Chrisman et al., 2010).

Finally, empirical evidence from the first four editions of the annual Italian Observatory on medium and large family-controlled firms (in collaboration with AIdAF, The Italian Association of Family Firms, Unicredit Bank, and the Chamber of Commerce of Milan) suggest additional research topics for the near future. Consistent also with the theoretical review above, these topics include the following: (1) Family firms' heterogeneity, which should stress the importance of critical dimensions such as firm size, ownership concentration, generation in command, and family pervasiveness at different leadership levels. The adoption of a configurational approach would be of help to reassess all the traditional issues of family business investigation (including the effects of governance, leadership, succession, strategy, and performance) into specific configurations or 'types' of family firms. (2) Leadership (or coleadership) models: the limited attention to coleadership is surprising in light of the importance of coleadership in family firms from a conceptual standpoint, as well as in terms of magnitude of the phenomenon. Conceptually, family business literature indicated coleadership as a leadership model particularly suited for family firms at different stages of the firm development and/or generations. Coleadership may occur among cofounders, with parents, brothers, or cousins, who share the responsibility to lead a new venture. (3) Multilevel analyses: most family business studies followed the tendency in the broader strategic management literature to investigate the impact of managerial characteristics on firm outcomes, and this tendency has been replicated in the family business field. Nevertheless, the intrinsic interplay among actors (family and nonfamily) within family firms, and the sophistication of analytical techniques and new statistical tools allow now for the possibility of further delving into this, and more attention to multilevel investigations should be devoted. (4) Family firms' behaviors: future research may benefit from considering more in-depth behaviors of family firms and family actors. Again, behaviors can be effectively investigated in different types of family firms, and include entrepreneurship (in smaller firms), corporate social responsibility, or stakeholder attention, as well as more strategic issues such as adaptability and responses to changing environments.

On the other hand, proper investigation of these issues open important methodological challenges. First, the vast majority of existing studies relied on a rather limited set of variables, including family control and family leadership mostly. Despite the challenge posed by measurement issues, future studies should propose research designs that take into account the need to go beyond simple – although powerful – variables such as family ownership and leadership. The more accurate test of constructs related to behaviors of various family and nonfamily actors inside family firms would also be of extreme help to solve some of the theoretical tensions between economic- or psychological-based theories discussed above, and to allow a better investigation of family firms' and family actors' behaviors. At the same time, however, the will to more deeply investigate family businesses raise concerns on information availability. Entrepreneurs and their families are known to be very reserved and protective of their privacy. Moreover, most family businesses do not have to disclose much information about their structure or about their performances. Researchers are trying to overcome this problem by collaborating with institutions such as banks that can provide family business databases or by designing research projects based on primary sources and making use of interviews, questionnaires, and longitudinal case studies. Sponsorship will also be essential for this purpose: the strong link with family businesses and institutions will be more and more helpful in making the relationship between theory and practice mutually beneficial, and to fund large, cross-country databases. Obviously scholars should avoid focusing on short-term needs and commit themselves to identifying long-term research goals and strategies.

Abstract

Sociolegal scholars maintain that the role of family law is to promote the 'institutionalization' of the family. Institutionalization involves the creation of normative expectations, the coordination of behavior, and the regularization of roles associated with family formation, conduct, and dissolution. Two long-term developments currently are reshaping families and transforming family law: greater autonomy for women and growing economic inequality in Western societies. These changes have eroded the formerly near-universal view of marriage as the only appropriate site for childbearing. Growing inequality has created a menu of options in family formation that are importantly shaped by class. Cherlin (2004) sees the growth in nonmarital cohabitation and same-sex unions, as representing the 'deinstitutionalization' of American marriage. Such normative 'innovations' have also been viewed as undermining the very institution of family.

Introduction

Sociolegal scholars maintain that the role of family law is to promote the 'institutionalization' of the family. Institutionalization involves the creation of normative expectations, the coordination of behavior, and the regularization of roles associated with family formation, conduct, and dissolution. Carl Schneider (1992) described this institutionalization as accomplished through the 'channeling function' of family law. Law's channeling in the family context is less coercive than it is in, for example, criminal law, but more directive than the reliance on voluntary assumption of obligations found in areas such as contract law.

Two long-term developments currently are reshaping families and transforming family law: greater autonomy for women and growing economic inequality in Western societies. These changes have eroded the formerly near-universal acceptance of marriage as the only appropriate site for childbearing. Growing inequality has created a menu of options in family formation that are importantly shaped by class. Today, marriages tend to occur much later in life, if at all. Some commentators suggest marriage has become a 'status symbol,' attainable only by those who have achieved both maturity and financial stability.

Sociologist Andrew Cherlin (2004) has also noted a move away from the social norms that once guided young people into marriage and kept them there. These norms imposed gendered roles that marked entry into adulthood across society (and which also fostered the dependence of wives on wage-earning husbands). Modern relationships are seen as part of a quest for individual expression and fulfillment rather than societally mandated institutional obligations. Cherlin describes related societal changes, such as the growth in nonmarital cohabitation and same-sex unions, as representing the 'deinstitutionalization' of American marriage. Such normative 'innovations' in coupling have also been viewed as undermining the very institution of family.

The Traditional Family of the Industrial Era

The 'traditional' family is the middle class family of the Enlightenment and the manufacturing era (Carbone, 2000). The industrial age, with greater urbanization and an expanded middle class, remade the foundations of family life. Marriage was no longer an arranged affair that cemented the property ties between two families, but a more voluntary enterprise in which the couple made choices for themselves (Stone, 1977; Coontz, 2006). In the process, women's roles were transformed. No longer subordinate to their husband's oversight of the family's commercial and personal production, wives were mistresses of a remade, middle-class domestic realm. The family ideal changed from that of an independent 'little commonwealth' (Grossberg, 1985) to a 'haven' charged with the moral instruction of the young and maintenance of the family's spiritual keel (Lasch, 1995).

At the height of these changes in Europe, philosophers like Immanuel Kant and Friedrich Hegel struggled to rationalize family bonds resting on the agreement of the couple, rather than the wisdom of their elders. Kant argued that marriage must be understood as a contract in which a man and a woman give themselves to each other unconditionally for life to satisfy the principle that people should be treated as ends in themselves rather than means to an end. Hegel resisted Kant's use of 'contract,' and asserted that if marriage were to be understood as compact, it was an agreement that transcended the limited perspective of contract. He maintained the complementary natures of male and female merged in marriage, creating a new union greater than the sum of the two individuals. The couple's commitment to each other was not merely a private compact they could dissolve at will, but a compact that united the couple with the community in a shared enterprise.

Notwithstanding their disagreements, Kant and Hegel agreed that the family necessarily rested on marriage, which was defined as the permanent union between one man and one woman. The relationship needed to be indissoluble in nature, a commitment to the community by the couple that accepted responsibility for the consequences of their sexual relationship, particularly pregnancy and childbirth, with their accompanying economic and social burdens. The marital family was the societal institution whereby dependency was privatized (Fineman, 2004). This new family ideal set the stage for greater policy emphasis on the nuclear family, as well as fostering greater middle class investment in children (Carbone, 2000).

The legal institutionalization of the marital family was bolstered by laws punishing and stigmatizing nonmarital cohabitation, fornication, and child-bearing. Other laws burnished marital commitments by making divorce extremely difficult, tying paternity to the marital family, and confining women's social and economic roles largely in terms of their marital roles as wife and mother. Within this system, the universality of marriage rested upon gender inequality. Conservative commentator William Kristol (1991) observed that for marriage to work women must be taught "to grasp the following three points: the necessity of marriage, the importance of good morals, and the necessity of inequality within marriage." Feminist Adrienne Rich (1980), writing a decade earlier, similarly explained that, "[w]omen have married because it was necessary, in order to survive economically, in order to have children who would not suffer economic deprivation or social ostracism, in order to remain respectable, in order to do what was expected of women."

Family law reinforced gendered expectations, and the subordination that accompanied them. Notions of family privacy cloaked violence that occurred behind closed doors (Fineman, 1995). Forcing unwed mothers to put their children up for adoption held the line on single parent families (Solinger, 1992). Family law for the wealthy and sophisticated allowed them to manage relationships on their own terms, (Mnookin and Kornhauser, 1979) while the poor who failed to realize the marital ideal of 'independence' and 'self-sufficiency' became visible in highly stigmatized systems of social welfare (Tenbroek, 1965; Fineman, 1995).

The 'Deinstitutionalizing' of the Traditional Family

The deinstitutionalization of the family occurred in response to three 'revolutions' that took place in the mid-twentieth century: the gender equality, sexual liberation, and no-fault divorce movements. These forces redefined the relationship between men and women, remade expectations for work and family, and decoupled marriage and reproduction (Jacob, 1988).

During the late 1960s and early 1970s, states in the United States began to lower the age of political majority from 21 to 18. This culminated in a constitutional amendment that lowered the age of majority on a national level, and eventually a Supreme Court ruling that extended the privileges of adulthood to teens. This change in the legal age had the inadvertent effect of making the newly available birth control pill legal on college campuses without parental approval. Economists Goldin and Katz indicate that the greater availability of the pill correlated with a significant delay in the age of marriage, women staying in school longer, and a dramatic increase in female enrollment in graduate and professional schools (Goldin and Katz, 2002). The legalization of abortion in 1973 saw adoptions, which peaked in 1970, cut in half by 1975 as teen births steadily declined.

These changes had a profound effect on family formation. First, education increased women's independence – even the mothers of small children could conceivably support themselves. Second, as women directed more energy to market labor, men were expected to contribute more to childrearing. Third, women gained greater control over their own sexuality, as much of the stigma associated with nonmarital sexuality was removed and pregnancy prevention became accessible. The transformation of women's roles that came with the waning of the industrial economy prompted a revolution in family law (Jacob, 1988).

The divorce law of the industrial era permitted marital dissolution only if one party (and one party alone) was at 'fault.' Flouting well-defined marital obligations justified freeing the other spouse from the bonds of what was seen as an already defunct union. If both parties were at fault, however, neither could obtain a divorce. Perhaps in light of the growing independence of women, demand for divorce rose. Spouses colluded and 'divorce factories' rose up to help them (Jacob, 1988). It was said that adultery was proved with certainty only where it had not occurred, as where one of the spouses might agree to be photographed with a paid model outside a hotel to 'prove' that divorce grounds existed. These practices discredited the process and increased the demand for divorce reform over the course of the twentieth century. When the dam obstructing reform efforts gave way, divorce reform swept the United States, with every state liberalizing the grounds for divorce between 1969 and 1985. The incidence of divorce grew dramatically, and single parents became a common occurrence.

As the stigma associated with nonmarital sexuality declined, so did the legal distinctions between marital and nonmarital children. In England, 'illegitimate' children were said to be *filius nullius*, literally, the child of no one, unable to inherit from their mother or father. In 1972, the US Supreme Court struck down state laws distinguishing between marital and nonmarital children with respect to inheritance (*Levy v. Louisiana*). In the same year, it also held unconstitutional the refusal to recognize as a legal parent an unmarried, biological father who had lived with the mother and children (*Stanley v. Illinois*). In the years that followed, family law eliminated most of the remaining distinctions between marital and nonmarital children.

Finally, custody law shifted from a model that presumed that children of tender years would be better off with their mothers, to one that assumes that children benefit from the continuing involvement of both parents. This legal shift dismantled the gendered roles of 'mother' and 'father' and replaced them with a more neutral parenting model.

The Emergence of Marriage as a Marker of Class and Legal Parentage as the Foundation of Family Law

The evolution in women's roles produced a fundamental change in the ways in which men and women match up in the choice of long term partners. Between 1960 and 2000, both men and women increased the emphasis they placed on a prospective partner's earning potential (Stone et al., 2007), with a much more dramatic change seen among men. During the same period, the degree of 'assortative mating,' that is, the tendency to marry partners with similar levels of education and income, has increased substantially (Schwartz, 2013). In addition, the average age of marriage has risen (Hymowitz et al., 2013) and, with a later age of marriage, it is easier for potential mates to determine who will realize their youthful

promise and who will fail to meet societal expectations for success. Taken collectively, these changes mean that investment in education and income potential pays off not only in terms of career potential, but in terms of both men and women's attractiveness to potential partners.

Paralleling these changes, however, has been a dramatic increase in income inequality, with a greater differential among men than among women. Significantly, at the bottom of the income distribution, men are losing ground, as employment opportunities for the less skilled have declined and employment stability has been harder to come by (Carbone and Cahn, 2014). In addition, the gendered wage gap between men and women, which in 1990 was smaller for female college graduates, today has increased substantially for the most highly educated women, even as it has been shrinking for other groups (Carbone, 2000). Changes in both income and inequality have remade the marriage market. At the top of the income distribution pyramid is a large group of successful men who would like to marry the small group of elite women. At the bottom, chronic unemployment and mass incarceration render a large number of men effectively unmarriageable. In the middle, women's income and employment stability have improved, while the fortunes of comparable men have worsened.

While attitudes about gender roles have become more flexible (Amato, et al., 2009), 'gender performance' remains important in mate selection and both men and women agree that a man who cannot hold a steady job is not a good marriage prospect (Cherlin, 2009). Further, while both men and women would like to marry someone who earns about what they do, many feel more comfortable if the man is the higher earner. The couples who report the highest marital quality manage either dual earner or male primary breadwinner relationships; working class couples where the wife works outside the home more than she would like because the husband cannot earn enough are among the most divorce prone (Amato, et al., 2009).

Taken together, greater inequality and persistent gender performance expectations have made it more likely that the women at the top will find an attractive spouse than the women at the bottom, while the women in the middle seek to pair with a shrinking group of 'comparable' men. The result remakes the terms of adult relationships, and family law ratifies the new terms, but often indirectly. In the meantime, the top, the bottom, and the middle play out their differences in terms of the legal connection to children.

The Redefinition of Adult Ties – From Dependent to Interdependent

Marriage in the industrial era was premised on female dependence; women had relatively little power within marriage (Okin, 1991) and, at divorce, the common law system typically allowed the men to retain the majority of the family's assets while the women might receive support. The common law system accorded property at divorce in accordance with title. Thus, women reclaimed any property they held before the marriage or through gift or inheritance and men kept the property produced during marriage and titled in their names. Couples might choose to put some assets, such as the family home, in their name jointly and if they did such assets would be split at divorce. Community property states, in contrast, treated all property acquired as a result of the marital couples' labor as jointly owned, irrespective of title (Harris et al., 2009).

Marriage in the information age, in contrast, is premised on interdependence (Cahn and Carbone, 2010). Husbands and wives are expected to commingle their assets and efforts; at divorce, these contributions are presumed to be equal and subject to equal division. Support, if it awarded at all, tends to be short term and transitional (Fineman, 1991; Baker, 2010). The new system treats men and women as equally capable of self-support and assumes that even long-term homemakers will reenter the labor force following a breakup.

At the same time, men and women are both expected to contribute to child care. While the 'best interest of the child' remains the lynchpin for custody awards, almost all US jurisdictions presume that continuing contact with both parents is in the child's interests. Some jurisdictions create a presumption in favor of 'joint custody,' that is, the award of legal decision-making power (joint legal custody) and shares of the child's time (joint physical custody) to both parents (Fineman, 1991). Some states have even considered a presumption in favor of shared custody principles that attempt to award roughly equal periods of time with each parent. Other states, while not necessarily favoring joint or shared custody, have enacted 'friendly parent' provisions that presume it is in the child's interests for the parent most likely to facilitate the involvement of the other to receive primary custody. In accordance with these principles, almost all parents who pursue the issue receive at least visitation; parents involved in violence, abuse, or dangerous behavior may still receive supervised visitation that allows them to spend time with the child under the supervision of a third party such as the grandparents, or in more serious cases, a trained supervisor (Meier, 2003).

Child support, in turn, has become set in accordance with relatively mechanical formulas based on both parents' income. Most states automatically adjust support in accordance with the amount of time the child spends with each parent. Increasingly, emphasis on shared custody reduces the amount of support paid to the other parent as the courts assume that each custodial parent devotes resources to the child's care while the child is in that parent's custody.

The more egalitarian nature of the law of marriage and divorce no longer assigns marital roles, support obligations, or child care responsibilities in accordance with gender stereotypes. This change in norms has also facilitated greater recognition of same-sex marriage as prohibitions on the recognition of same-sex loving relationships become pointless and punitive. Some argue that the dismantling of explicit gender roles undermines marriage and contributes to its deinstitutionalization (Cherlin, 2004). Others maintain that the recognition of same-sex unions helps remake marriage in terms of a modernist emphasis on flexible roles rather than an insistence on traditionalist or religious dictates (Cahn and Carbone, 2010; Rauch, 2010).

The transformation of marriage has also affected the willingness to marry. In 2013, a study of 18- to 29-year-old cohabitants found that better educated men and less educated women expressed the greatest reluctance. Among those without a high-school diploma, 67% of men versus only 47% of women said that they expect to marry their current partner.

Among those with at least some college, in contrast, 68% of women versus only 46% of men expected to marry their current partner (Hymowitz et al., 2013). Better educated men often hope to 'do better,' especially if their current partner does not share a similar level of income or ambition, and they are wary of early commitments that might distract them from their career objectives (Regnerus and Uecker, 2011). Yet, once they do commit, an interdependent marriage model gives them greater security than one that presumes wives' dependence. Premarital agreements that protect the assets of the higher earning party, more typically the male among elite couples, have become more common, and more likely to be enforced (Younger, 2007). Marriages of relatively short durations sometimes trigger spousal support limitations. Some states expressly restrict long-term support to marriages longer than 10 years and other states do so through judicial decisions (Baker, 2010). Moreover, the preference for shared custody arrangements protects male rights in children. Women initiate roughly two-thirds of divorces and they are less likely to do so in states that routinely award joint custody (Brinig and Allen, 2000). For all couples, the share of male custodial time with children has increased, and the more income the father has, the less likely the mother is to receive sole custody after a break-up (Brown and Cook, 2012).

The fact that well-educated women can find acceptable men and that men enjoy greater protections within an interdependent marriage model has increased the emphasis on marriage among American college graduates. This group marries relatively late, but continues to raise children primarily within marriage. The top 10% of women measured by income used to be among the least likely to marry; at the end of the twentieth century, they were the only group not to see their marriage rates decline in comparison with 1970 levels (Looney and Greenstone, 2012). For college graduates as a group, divorce rates in 2004 had fallen back to the levels of the mid-1960s, before the enactment of no-fault divorce (McLanahan, 2004). In 2006–08, white female college graduates had the same nonmarital birth rate they did in 1982 (2%). And for both whites and African-Americans, the likelihood that a 14-year-old girl was living with both parents rose between the early 1980s and the first decade of the twenty-first century (Wilcox and Marquardt, 2010). For everyone else, however, divorce, nonmarital births and relationship instability continued to rise.

Interdependent marriage, while attractive to the top group in society, poses a threat to others, and particularly to the increasing number of women in relationships with less reliable men. Male layoffs, job instability, low wages, contacts with the criminal justice system, violence, and substance abuse all contribute to the likelihood that a relationship will end, and all have increased for working class men since the mid-1980s (Murray, 2013). These factors, which were once concentrated among isolated groups such as inner city African-Americans, today affect a larger percentage of society and have decreased the supply of marriageable men. Moreover, women's share of housework follows a U-shaped curve. The more income a woman makes the less housework she does – up to the point where she earns more than her husband and then she does more (Schneider, 2011). The likelihood that a husband earns more than the wife in turn corresponds to class: in families with dual earners, the wife earns more than the husband in 70% of marriages in the bottom quintile of families, in comparison with 34% of wives in families with incomes in the top 20% (Glynn, 2010). Working class women have thus become more likely to be both the more reliable breadwinner *and* the primary caretaker. They are also more likely than men to decide to end a relationship. If they were to marry their partners and divorce, they would find that (1) it is more difficult to sever ties premised on interdependent finances; (2) the assets to be divided in the settlement, however meager, may be ones they think of as 'theirs' and/or as the assets on which they are relying to provide for their children; and (3) husbands are more likely than other fathers to receive shared custody (Brown and Cook, 2012). In these circumstances, less educated women have reason to be wary about marriage. While the divorce rates of college graduates declined after 1990, those without college degrees continued to rise at least until the financial crisis. Marriage rates for the same group declined and declined even more after 2007, and nonmarital births have steadily increased over the last 30 to 40 years.

Those who have children together without marrying describe their relationships in contingent terms rather than in terms of the unconditional commitment that Kant and Hegel described as the hallmark of marriage. Men and women often view each other with a measure of distrust, the men wary of women who expect a meal ticket and the women distrustful of the men's fidelity and reliability (Burton et al., 2009; Edin and Nelson, 2013, Wilson, 1987). These couples distinguish marriage – and its requirement of unconditional commitment – from cohabitation, and the differences in behavior correspond to the differences in attitudes. Married spouses are more likely than cohabitants to visit each other in prison, to stay together through difficult times, and to share child-rearing responsibilities (Braman, 2007; Bowman, 2010). Cohabitants engage in shorter term, more transactional exchanges. Mothers tend to stay with fathers so long as they contribute financially, remain faithful, avoid violence and criminality, and help with the child (Baker, 2010; Edin and Nelson, 2013). If the mothers do not support the fathers' involvement in the child's life, the father moves on to a new partner and often new children (McLanahan, 2004).

In this system, marriage is simply one of a number of choices about how to structure adult relationships. Pregnancy and childbirth do not necessarily imply an obligation to marry, stay together or even share childrearing responsibilities. Instead, couples individually negotiate the terms of their relationships. The more critical (and less individual) legal determination becomes the establishment of parentage.

The Primacy of the Parent–Child Tie

In the industrial era, unmarried motherhood was suspect and commanded little support. Legal paternity, in turn, did not automatically follow from biology. Instead, it required marriage. Today, legal motherhood ordinarily follows from childbirth, with the principal exception involving use of a gestational carrier (Harris et al., 2009), while legal fatherhood can be established through marriage, voluntary acknowledgment, or a paternity action. The combination of DNA testing and relationship instability, however, has made explicit that

which was hidden in other eras: biology and functioning as a parent do not always coincide. When they do not, there is a choice to be made as to which tie – biology or function – should be the basis for an allocation of decision-making power.

Marriage, both historically and today, facilitates paternity establishment. When a married woman gives birth, the husband is treated as the legal father even if neither husband nor wife takes any steps to secure official recognition. (The birth certificate, whether it names or fails to name a father, constitutes evidence of legal parentage, but it does not in itself establish either biological or legal parenthood nor necessarily serves as a barrier to a later challenge.) If the two divorce, the court will ask the couple to list any 'children of the marriage' and will not grant the divorce without an order allocating responsibility for the children in terms of both custody and support. That order, in turn, may collaterally estop each of them from later denying the husband's parental status (Carbone and Cahn, 2011). Historically, the opportunities to challenge the fact of the husband's biological paternity were limited. Both historically and today, if no one brings such a challenge, the husband remains the child's legal father irrespective of the circumstances of the child's conception.

An unmarried father, in contrast, did not historically have rights as a legal parent. He could not seek custody or visitation or prevent the mother from placing the child for adoption. While he could be held responsible for support, the ability to seek support rested with the state, rather than with the mother, and was used in an effort to offset the resources the state provided to the child (Harris et al., 2009). A man who cared about his child was expected to marry the mother or to forego any say in the child's life. Indeed, as recently as in Georgia, the only way to establish paternity outside of marriage was for the mother to swear out a criminal arrest warrant in 'fornication and bastardy' against the father.

The increase in nonmarital births and growing public expenditures for the Aid for Families with Dependent Children program led the US government to provide incentives for states to streamline paternity establishment. In the middle of the twentieth century, a pregnancy, particularly among whites, typically triggered a decision to marry or break-up. By the 1990s, unmarried mothers of all races had become more likely to be in a continuing relationship with the father, and the father had become more likely to be present with the mother at the hospital at the time of the child's birth (McLanahan, 2004). The states, recognizing these patterns, provided for 'voluntary acknowledgments of paternity' to be signed by both mother and father preferably before the child left the hospital. The acknowledgments had the force of a paternity judgment without either a court action or a paternity test (Harris et al., 2009). Like the marital presumption, they established legal parentage based on a presumption of biological paternity. Whatever the facts, the presumption remained in force absent an action to rescind the acknowledgment, in accordance with the limited circumstances and time periods provided by the statutes.

In addition to these provisions, the alleged father, the mother, or the state can initiate a paternity action to establish parentage. These actions typically require a DNA test to establish biological parentage. The state often brings such actions to compel child support payments, particularly for children receiving state benefits. Fathers also bring such actions to establish their legal status where the mothers will not cooperate with a voluntary acknowledgment.

These procedures exist to secure recognition for biological parents. Historically, adoption served as the only way to recognize an adult as a legal parent outside of a presumption of biological parenthood. Today, however, several states recognize parental status on the basis of 'functioning like a parent.' California, for example, extends a presumption of parenthood to those who "welcome the child into their households and hold out the child as [their] … own." While the statutory provision had been initially treated as a presumption of biological paternity, the California Supreme Court ruled in 2002 that proof that the presumed father was not the biological father did not necessarily rebut the presumption (*In re Nicholos H.*). In subsequent cases, the court has extended the presumption to women as well as men and indicated a clear preference for recognizing those who have assumed parental functions over those whose parenthood was based on either biology or marriage alone (Carbone and Cahn, 2014). Other states have similarly recognized parentage on the basis of function, under the labels of *de facto* or psychological parenthood or parenthood by estoppel. The courts nonetheless tend to give more weightage to biology in establishing responsibility for support while giving more weightage to function in granting rights to custody or visitation (Harris et al., 2009).

Class and Parental Ties

Taken together, these provisions for establishing parenthood parallel the class-based changes in marriage. Where couples marry before they have children, the mother effectively consents to the father's continuing involvement in the child's life. Paternity establishment follows automatically, the father has substantial rights over the child that the courts allocate automatically in the event of divorce, and fathers in fact invest more time and money in their children.

Where the parents sign a voluntary acknowledgment at the time of the child's birth, the parents typically expect mutual involvement in the child's life and, in fact, these fathers are more likely than the fathers who do not sign voluntary acknowledgments to continue to see the child after a break-up with the mother and to pay support voluntarily (McLanahan, 2004). While voluntary acknowledgments establish paternal rights identical to those established through marriages or judgments, they are less likely to lead to custodial orders granting the child time with the father. In the absence of marriage, the couple may go their separate ways without any involvement with the courts and without any allocation of custody rights. Instead, they tend to end up in court only if the custodial parent seeks support or if the noncustodial parent seeks a share of the child's time. Particularly if the child receives state benefits, the state may help with child support enforcement, but there is rarely much if any assistance in securing custodial rights. Going to court may be costly and enforcing a subsequent judgment difficult.

The same factors hold with even greater force to those who do not sign voluntary acknowledgments. If the mother refuses to acknowledge the father, the father must bring a court action

that will turn on a paternity test. The tests can cost several hundred dollars in themselves.

Custody statutes no longer distinguish between married and unmarried fathers, and legal parents who go to court can expect to receive custodial rights. The likelihood of doing so nonetheless corresponds with marriage – married fathers are dramatically more likely to have a custodial order giving them a share of the child's time than unmarried fathers, and those with voluntary acknowledgments are more likely to have such orders than those with paternity judgments (Brown and Cook, 2012). In addition, while the state facilitates child support enforcement, state-initiated actions have proven to be counterproductive in encouraging greater paternal involvement. Instead, fathers are more likely to remain involved with their children through cooperation with the mother; involuntary enforcement actions often increase the conflicts underlying such relationships and undercut the relationship with the child (Harris, 2011). Racial differences in relationship stability narrow or disappear once the ratio of men to women is taken into account; cultural differences, however, affect continuing contact with the child. The involvement of white fathers continues to depend more on a continuing relationship with the mother while African-American fathers' relationship with the child is more likely to be independent of adult ties, though the differences between the two groups are narrowing.

A contentious issue underlying parentage is the continuing status of the marital presumption. Courts in Texas and Kentucky acknowledge that an uncritical application of the marital presumption allows the mother to decide who the father will be and, indeed, in some Kentucky cases the mother appears to have married or remained married primarily to cut the biological father out of the child's life (Carbone and Cahn, 2014). These states have made it easier for biological fathers to challenge the presumption. In contrast, Utah and Louisiana tend to apply the presumption primarily to reward faithful husbands over 'adulterous' fathers, but have made it easier for husbands to challenge paternity at or after divorce. California, on the other hand, acknowledges that the marital presumption gives the mother effective decision-making power, but continues to apply the presumption in the context of a preference for upholding the parental rights of those who have assumed parental functions. A few states have begun to recognize more than two parents, including Louisiana and California, but it remains to be seen how these developments will affect recognition of step-parents.

All of these decisions involve a regulation of the mother's decision-making power. With marriage, the mother can be said to have consented to her husband's parental role. Giving voluntary acknowledgments, she consents to paternity, but without any necessary understandings about the terms of the relationship. Where paternity has not been established, the mother's decision to end a relationship typically ends the father's involvement, unless he satisfies her terms for continuing involvement with the child (Edin and Nelson, 2013). The California cases accept the mother's ability to choose the second parent, but limit her ability to change her mind later. The Texas and Kentucky decisions subject the mother to the biological father's ability to demand a role in the child's life – if he can succeed in getting to court and enforcing a judgment.

The irony is that these developments simultaneously make formal family law more supportive of fathers' rights and make the ability to enforce them more dependent on fathers' income and status. The better educated male cohabitants who express skepticism about their partners do so because elite men have become pickier about their choice of spouses, but the law enforces their rights once they do marry. Less educated women have become warier about marriage because they enjoy a smaller choice of reliable men in the context of more interdependent relationships. Less elite men report, in turn, that "[i]n a startling reversal of the way gender typically operates in American society, unwed childbearing seems to offer mom, and not dad, all the power: 'it's her way or the highway,' in the words of one father" (Edin and Nelson, 2013).

Conclusion

Were this simply a matter of personal choice, the consequences might be termed "postmodern family" law (Stark, 2001) and the creation of greater family variety celebrated as personal expression. The class-based nature of these changes, however, should be cause for concern as they skew the allocation of resources to the next generation. Class-based differences in family resources have grown dramatically. In 1970, for example, college graduate and high school graduate parents spent about the same amount of interactive time with their children. By 2000, however, college graduate parents were spending dramatically more time with their children than the less educated. In 1970, parental education made a difference in children's performance, but income-based differences were relatively small. In contrast, today income differences have grown dramatically even among parents with the same education, producing even greater gaps in cognitive performance and children's well-being (Reardon, 2011).

The state has responded to these developments by making them worse. State policies increase the advantages of those with the most income and the neoliberal state has reduced rather than increased the assistance to low income families. The result recreates reduced social mobility and threatens to impoverish the lives of the next generation.

Abstract

This article reviews empirical evidence on the microlevel consequences of family planning programs in middle- and low-income countries. In doing so, it focuses on fertility outcomes (the number and timing of births), women's health and socioeconomic outcomes (mortality, human capital, and labor force participation), and children's health and socioeconomic outcomes throughout the life cycle. Though effect sizes are heterogeneous, long-term studies imply that, in practice, family planning programs may only explain a small share of fertility decline in real-world settings. Family planning programs may also have quantitatively modest – but practically meaningful – effects on the socioeconomic welfare of individuals and families.

Introduction

The twentieth century witnessed the birth of modern 'family planning' and its evolution from an early target of antiobscenity laws (Comstock, 1873) to a focus of global efforts to improve human welfare (Cleland et al., 2006). Many observers date the modern family planning movement to the famous 1916 opening of New York City's first birth control clinic. Mid-century, the International Planned Parenthood Federation and the Population Council were instrumental in both the development of modern contraceptive technologies (including the first oral contraceptive, Enovid, and plastic intrauterine devices) and in promoting their widespread distribution, ushering in the 'modern' era of fertility control.

Heightened concern about world's unprecedented rate of population growth (and its potential macroeconomic and environmental consequences) also arose mid-century (Coale and Hoover, 1959) – and Neo-Malthusian alarm grew in tenor with Paul Ehrlich's publication of *The Population Bomb* in 1968. In response, aid agencies including USAID and the World Bank joined with the Population Council, the International Planned Parenthood Foundation (IPPF), and others in supporting the establishment of large-scale family planning programs worldwide. Global funding for family planning tripled during the 1970s and early 1980s – and by the mid-1990s, large-scale family planning programs were active in 115 countries (Cleland et al., 2006). Remarkably, the total fertility rate in developing countries also fell by more than half over this period (Sinding, 2007).

Academics have long debated the primary forces responsible for global fertility decline – and in particular, the contribution made by family planning (Kaiser, 2011). One view largely credits family planning programs directly (Bongaarts et al., 1990; Robey et al., 1993). Others give them less credit, arguing that fertility decline is a response to economic development and industrialization, even if aided by family planning programs (Becker, 1960; Davis, 1967; Voigtlander and Voth, 2013). A third view, promoted in part by the European Fertility Project (although its methodology has been debated (Brown and Guinnane, 2003)), emphasizes the importance of social networks that facilitated the diffusion of 'cultural innovations' including the social acceptability of small families (Coale and Watkins, 1986). Finally, some propose that falling mortality rates play a central role (Palloni and Rafalimanana, 1999).

As dire predictions about Malthusian demographic catastrophe failed to materialize (Lam, 2011), population policy became more nuanced during the 1980s and 1990s (Kelley, 2003). (Recognition of the importance of population age structure, not just population size and growth, grew during this period, and includes work on the 'demographic dividend' (Bloom and Williamson, 1998; Bloom et al., 2003; Bloom and Canning, 2009). Stances on the relationship between population growth and economic development became more neutral (Finkle and Crane, 1985), changing the motivation for family planning programs. At the 1994 International Conference on Population and Development in Cairo, macroeconomic rationales for population policy were replaced with feminist, rights-based frameworks. Family planning programs were recast to emphasize individual needs and desires, stressing socioeconomic and health benefits for women their families (Glasier et al., 2006). Also, as the definition of reproductive health expanded, so did the scope of family planning programs - growing to encompass safe delivery, prevention and treatment of sexually-transmitted infections, safe abortion, and violence against women (Greene and Merrick, 2005).

In the spirit of contemporary emphasis on broad, individual- level benefits, this article reviews empirical evidence on the microlevel consequences of family planning programs in middle- and low-income countries. In doing so, it focuses on three types of outcomes: (1) fertility outcomes (the number and timing of births), (2) women's health and socioeconomic outcomes (mortality, human capital, and labor force participation), and (3) children's health and socioeconomic outcomes throughout the life cycle. Importantly, we omit studies that simply estimate the effect of family planning programs on contraceptive use and knowledge, and we also omit studies that simply relate the number, timing, and spacing of births to downstream socioeconomic outcomes (given debate about the influence of family planning programs on fertility).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.31036-4

The remainder of this article is organized as follows. Section Background Controversy: Supply vs Demand and the Pritchett (1994) Critique summarizes background debate about the relative importance of supply- vs demand-side factors in explaining fertility decline. The third section reviews empirical studies of the relationship between family planning programs and fertility outcomes, while the fourth covers program effects on health and socioeconomic outcomes among women and their children. Pooling across studies, the fifth section concludes by summarizing ranges of estimates that emerge from the empirical literature. Overall, family planning programs may explain only a small share of the fertility decline in real-world settings, but it may also have meaningful effects on the socioeconomic welfare of individuals and families.

Background Controversy: Supply vs Demand and the Pritchett's (1994) Critique

Among the competing explanations for fertility decline described above, an important distinction emerges between demand- and supply-side factors. While there is little debate about the association between use of modern contraceptives and fertility, the underlying determinants of contraceptive use are controversial. The crux of the debate pits the relative importance of changes in the demand for children (and for contraceptives) against changes in the availability and price of contraceptives (generally accomplished through family planning programs). Before reviewing microlevel empirical studies of family planning in Sections Family Planning Programs and the Number, Timing, and Spacing of Births and Family Planning Programs and Health and Socio-Economic Outcomes among Women and Children, we first summarize this controversy.

Lant Pritchett's 1994 article entitled "Desired Fertility and the Impact of Population Policies" published in *Population and Development Review* is a landmark paper in this debate. The paper challenges conventional wisdom about the centrality of contraceptive supply in determining total fertility rates in developing countries (Bongaarts et al., 1990). Pritchett begins by deconstructing the conceptual fallacy equating contraceptive prevalence (or use) to contraceptive supply (or availability). Because use is jointly determined by both supply and demand (and not by supply alone), the close relationship observed between a country's contraceptive prevalence rate and its total fertility rate fails to isolate the importance of either demand- or supply-side factors.

Across three different measures of desired fertility (or the demand for children), the article establishes a nearly one-to-one correspondence between a country's total fertility rate and the number of children that women report wanting (regression coefficients range from 0.78 to 0.95 – with a positive constant of about 1–1.5). Pritchett argues that these relationships demonstrate the primacy of demand and that contraceptive supply has little influence on a country's total fertility rate. He then addresses concerns about *ex post* rationalization and about the dependence of desired fertility on contraceptive availability using two related instrumental variables (IVs) methodologies. First, he uses the proportion of women with four children who desire no more (a forward-looking statistic free of ex post rationalization) to instrument for a retrospective measure of the demand for children fertility (DTFR). Second, he uses a retrospective measure of demand (DTFR) to instrument for a forward-looking measure (WTFR). The resulting IVs estimates are again close to one, which Pritchett interprets to strengthen the conclusion that women are essentially able to have the number of children that they want – and contraceptive supply can at best explain 10% of the cross-country variation in fertility rates.

Pritchett's IVs approach requires two important assumptions that we highlight to meet the necessary 'exclusion restriction' (Angrist and Kreuger, 1991). The first is that the share of women in a country who have a given number of children and report not wanting more is unrelated to the country's total fertility rate except through desired fertility (demand). When answering questions about wanting more children, if women have in mind the costs of fertility control that they actually face in practice (despite survey instructions to the contrary - Pritchett argues that DHS surveys aim to elicit information about desired fertility at zero contraceptive cost), this assumption would be violated. However, these costs may be difficult for respondents to disregard – the interpersonal costs that women face in bargaining over fertility with their partners, for example. The second related assumption is that past and current/future costs of fertility control are uncorrelated. Because such a correlation is plausible, current/future costs of fertility control could in fact be related to past fertility decisions. Ultimately, these assumptions are not directly testable.

On a more general level, Pritchett argues that the financial cost of modern contraceptives is too small relative to the importance of fertility decisions to exert meaningful influence. However, these costs may nonetheless be prohibitive for poor households facing tight credit or liquidity constraints, and importantly, the total cost of fertility control extends far beyond the financial cost of contraceptives – bargaining with spouses over fertility and direct disutility from using of contraceptive devices, for example – and some empirical evidence suggests that these costs may be substantial. On bargaining, Ashraf et al. (2014) show that among the subset of couples with different fertility preferences, offering vouchers for contraceptives to women privately is significantly more effective than offering vouchers to them in the presence of their husbands (reducing unwanted births by 57%). On the direct disutility of modern contraceptives, research on commercial sex markets suggests that men are willing to pay 23% more for sex without a condom (and double that for unprotected sex with attractive commercial sex workers) (Gertler et al., 2005).

Despite some unresolved concerns with Pritchett's (1994) analysis, its overarching point – that the demand for children may be more important than supply-side factors (including contraceptive supply) in determining fertility – may nonetheless stand. Important determinants of the demand for children studied in the empirical literature on fertility (which are not independent of each other) include infant and child mortality rates (Angeles, 2010; Kalemli-Ozcan, 2002; Schultz, 1985), the opportunity cost of time (both generally and for women) (Breierova and Duflo, 2004; Lavy and Zablotsky, 2011; Schultz, 1985), anticipated increases in future demand for human

capital (Galor and Weil, 2000), and women's bargaining power within households (Rasul, 2008).

Family Planning Programs and the Number, Timing, and Spacing of Births

The empirical literature on family planning is vast. To aid in this article, we used a strategy akin to the 'systematic review' methodology in the biomedical sciences, although we emphasize that we did not undertake a formal systematic review. Using explicit criteria to search four major databases of indexed journals (together with a 'snowball' approach), our initial search yielded 9501 studies for consideration. We then reviewed abstracts, applying inclusion criteria for methodological rigor, direct micro-level analysis of family planning program effects in developing countries, and an explicit focus on at least one of our three types of primary outcomes. For nonexperimental (observational) studies, we restricted this article to those using commonly accepted methodologies for addressing the role of confounding factors and endogenous program placement/intensity. These include (but are not limited to) conventional panel data techniques, difference-in-difference estimation, and IVs strategies using plausibly exogenous instruments. Our final list includes 28 studies meeting these criteria (see the accompanying electronic appendix (available at www.stanford.edu/~ngmiller) for details).

Randomized Controlled Trials

Arguably, the most prominent study of family planning conducted to date is the famous Matlab family planning experiment. Beginning in 1977, the experiment randomly assigned 141 villages in Matlab, Bangladesh to either the study's 'treatment' arm (70) or a control arm (71). In treatment villages, female reproductive health workers visited the homes of married women of childbearing age every 2 weeks to educate women about reproductive health, provide nutrition counseling, and offer modern contraceptives free of charge. Maternal and child health services were integrated into the experimental treatment in 1982 (Muhuri, 1995) and safe motherhood services followed (Chowdhury et al., 2009).

The Matlab experiment has produced a large volume of academic papers. Early papers report a 25% reduction in the general fertility rate over the first 2 years of the experiment (Phillips et al., 1982) and these reductions lasted throughout the 1980s (Foster and Roy, 1997; Koenig et al., 1992). Longer term follow-up suggests that these fertility effects persisted for at least 20 years, reducing the number of children ever born by 1–1.5 children and extending birth intervals by 8–13 months (Joshi and Schultz, 2007). Estimates of implied lifetime fertility reductions range from 13% (Sinha, 2005) to 23% (Joshi and Schultz, 2013).

The Matlab experiment has also generated debate. First, critics note that the intensity and expense of the program would be unrealistic on a large scale. In its first 10 years, program costs were approximately $180 per birth averted (120% of Bangladesh's GDP per capita in 1987) (Simmons et al., 1991) – nearly 10 times more than mean family planning spending in developing countries at the time (Pritchett, 1994). Second, bundling child health services into the family planning treatment effectively reduced the 'price' of child survival – and could have therefore exerted independent influence on fertility (Becker, 1991; Caldwell, 1976; Sah, 1991). Third, Schultz (2009) suggests that possible deviations from true randomization in the experiment's implementation.

There are few other randomized controlled trials of family planning services. The Navrongo experiment in Ghana studied 37 communities randomized across four treatment arms (Binka et al., 1995; Phillips et al., 2006). Although balance across arms was not achieved, treatment arms combining family planning service training and community outreach were associated with a 15% reduction in the total fertility rate among married women (Debpuur et al., 2002; Phillips et al., 2006). Effects on parity progression persisted for 15 years (and have largely been attributed to the promotion of contraceptive use through community organizations) but have declined over time (Phillips et al., 2006, 2012). Two other experiments integrated family planning services into existing programs: a microcredit program in Ethiopia (Desai and Tarozzi, 2011) and an HIV treatment program in Kenya (Kosgei et al., 2011). Both experiments find null results in the first few years following implementation.

Observational Studies

Two influential observational studies analyze contemporaneous effects of Indonesian National Family Planning Coordinating Board's programs during the late 1970s and 1980s. Gertler and Molyneaux (1994) combine birth history data with community-level information about family planning program activity to study program effects on community-level birth hazards between 1982 and 1987. Accounting for changes in the demand for children and community fixed effects, the authors show that family planning programs account for just 4–8% of Indonesia's decline in fertility (a 1–2% reduction in the monthly birth hazard) during the study period (Gertler and Molyneaux, 1994). Relatedly, using both survey and population census data and explicitly modeling village-level family planning program placement, (Pitt et al., 1993) fail to find that the program had any significant effect on fertility between 1976 and 1986.

Also estimating short-run program effects, two additional studies use strategies that exploit program variation due to idiosyncratic public finance rules governing local government resource allocation. Specifically, Molyneaux and Gertler (2000) find that family planning subsidies were associated with 3–6% lower quarterly birth hazards in Indonesia between 1985 and 1994. Studying family planning in Ethiopia, Portner et al. (2011) find that among uneducated women, the presence of a family planning program in a woman's 1990 district of residence was associated with roughly one fewer child ever born in the 1994 Ethiopian population census (a reduction of about 20% in this subgroup).

Other studies examine the cumulative effects of family planning programs over longer periods of time. To study the long-run effects of PROFAMILIA, Colombia's predominant family planning provider from 1965 until the 1980s, Miller (2010) combines 1985 and 1993 population census data with information about its staggered geographic expansion

across the country to estimate changes in fertility outcomes associated with age-specific program exposure. Controlling for cohort and birth area fixed effects as well as area-specific time trends, he finds that the presence of family planning services explains about 6–7% of Colombia's fertility decline over this period (postponing first births and reducing completed fertility by approximately 0.25–0.33 children).

Three studies by Angeles, Guilkey, and Mroz also use spatial and temporal variation in program exposure to estimate long-run effects on cumulative fertility. In Tanzania and Peru, the authors use random effects models to estimate the relationship between community-level program placement and individual birth hazards over two decades. They find 25–35% reductions in children ever born in Peru (Angeles et al., 2005a) and 10–20% reductions in Tanzania, reporting that half of these effects are linked to program exposure during adolescence (Angeles et al., 1998). In Indonesia, the authors model both indirect and direct pathways through which family planning might influence a woman's lifetime fertility. Jointly estimating equations for educational attainment, marriage, and fertility, they find that the long-term presence of family planning programs is associated with a 20% reduction in completed fertility (or about one child) (Angeles et al., 2005b).

Another set of studies examines the role of family planning in Iran's striking fertility decline during the 1980s and 1990s (as Iran's total fertility rate declined from over 7 births per woman to about 2 (Hashemi and Salehi-Isfahani, 2013)). Family planning was banned at the time of the Islamic Revolution, but in 1989, Iran abruptly legalized modern contraceptives and launched family planning programs through its large, preexisting cadre of community health workers (Behvarz). Salehi-Isfahani et al. (2010) combine data from the Iranian Ministry of Health with population census records from 1986 to 1996; using a difference-in-difference approach to study variation in the timing and location of community health worker activity, they find a 4% decline in the child to woman ratio associated with program activity, explaining 8–20% of the decline during the study period. Analyzing age-specific program exposure among cohorts of women in the 2006 Iranian census, Modrek and Ghobadi (2011) find an 18% reduction in children ever born among women first exposed to family planning between 20 and 34 years of age and a 28% reduction among women first exposed between 15 and 19 years of age. Using a similar approach, Hashemi and Salehi-Isfahani (2013) report that the presence of a program was associated with a 5–7% increase in birth spacing.

Finally, a recent group of studies examines the short-run consequences of unanticipated 'shocks' to family planning programs. We note that the interpretation of these papers' estimates is complex because longer-term fertility behavior (which may offset the consequences of short-lived shocks) is not observed. In Eastern Europe, where abortion was historically the predominant form of fertility regulation, many countries limited or banned abortion during the 1980s and 1990s. Examining the abrupt end of Romania's ban on abortion and family planning in 1989, Pop-Eleches (2010) uses survey data on births among reproductive age women 2 years before and after the end of the ban to employ a single difference approach (akin to a regression discontinuity design). The author finds that lifting the ban was associated with a 30% decline in fertility – and conducting simulations using his estimates, he suggests that the cumulative effect of the abortion ban was an increase of approximately 0.5 children (a 25% increase) among women who spent all of their reproductive years under the ban (Pop-Eleches, 2010).

Studying disruptions in the supply of free condoms to Filipino provinces due to supply chain irregularities, Salas (2013) finds that a 6% reduction in contraceptive supply is associated with a 15% increase in short-run birth hazard. Similarly, analyzing fluctuations in contraceptive supply in Ghana due to the instatement and repeal of the United States' "Mexico City Policy," Jones (2013) finds that the policy led to a 10% increase in pregnancies (or a 0.2 percentage point increase in the monthly pregnancy hazard) among rural women and women with little education.

Family Planning Programs and Health and Socioeconomic Outcomes among Women and Children

Beyond their impact on fertility, family planning programs may also have important health and socioeconomic benefits for mothers and their children (Canning and Schultz, 2012). Intuitively, these benefits could stem from changes in the number, timing, and spacing of births or from changes in sibship size and composition – but isolating the specific mechanisms or pathways through which they are produced is often not possible. Studying these benefits is also difficult because some do not emerge for many years, requiring long study periods.

Benefits among Mothers

Given high maternal mortality rates in many low- and middle-income countries, reductions in the number of births may mechanically reduce maternal mortality rates simply by reducing the number of times women are at risk of maternity-related death (Rahman and Menken, 2012). However, if family planning programs also selectively reduce the relative incidence of riskier pregnancies (such as higher parity births), they may also reduce the maternal mortality ratio (Cleland et al., 2012; Jain, 2011; Winikoff and Sullivan, 1987).

Few studies analyze the direct relationship between family planning programs and maternal mortality. One exception is an early study of the Matlab experiment reporting that the maternal mortality rate in treatment areas declined to about half of the rate in control areas between 1976 and 1985 (Koenig et al., 1988). However, this treatment effect was due to relative declines in fertility – there was no change in the maternal mortality ratio (and hence no change in average mortality risk conditional on pregnancy).

Among surviving women, long-term studies of the Matlab experiment find anthropometric gains associated with the treatment. Canning and Schultz (2012) report that in 1996, reproductive age women in treatment areas had a 1 kg m^{-2} higher Body Mass Index (BMI) than women in control areas. Adjusting for characteristics of women and their households,

Joshi and Schultz (2013) find that this BMI advantage among women in treatment villages is only present at older ages. However, they also find that women in treatment areas are roughly 2 kg heavier on average and are less likely to be underweight (defined as BMI<18 kg m^{-2}). In interpreting these findings, we emphasize that improvements in women's health could be due to bundling of women's health services into the family planning 'treatment' beginning in 1982.

By allowing women greater control over the number, timing, and spacing of births, family planning programs may also influence their educational attainment, labor force participation, and lifetime earnings (Greene and Merrick, 2005). Studying Colombia, Miller (2010) reports that the presence of a local family planning program early in women's reproductive years is associated with a 1% increase in educational attainment (0.05 years of schooling) and a 4–7% increase in the likelihood formal sector employment (1–2 percentage points). Using simulations, Angeles et al. (2005b) report larger effects on educational attainment in Indonesia, suggesting that lifetime exposure to family planning programs is associated with gains of 25–27% (or an additional 1.3 years of schooling).

Benefits among Children

Family planning programs could also influence children's health and socioeconomic outcomes through a variety of mechanisms (through changes in birth spacing and sibship size or through gains in women's educational attainment, for example). Although a large literature links various dimensions of fertility to child welfare (DaVanzo et al., 2005; Molyneaux and Gertler, 2000; Rutstein, 2005), few studies focus directly on family planning programs.

Studying child survival, two experiments find that family planning programs are associated with substantial reductions in child mortality under 5 years of age (decreases between 30% and 50%) (Joshi and Schultz, 2007; 2013; Phillips et al., 2006). However, we emphasize that these programs bundled family planning services together with other health services – and, in particular, ones targeting infant and child health, making it difficult to isolate the contribution of family planning services per se. Focusing more directly on family planning services alone, Miller (2010) and Portner et al. (2011) report no significant program effects on infant and child mortality.

Several other studies examine anthropometric measures of child health. Joshi and Schultz (2007) report that girls in Matlab's treatment villages have BMI z-scores that are 0.4 standard deviations larger on average than those of their control village counterparts. Studying children in the Philippines, Rosenzweig and Wolpin (1986) use longitudinal data to estimate within-child changes in anthropometrics associated with the share of a child's life for which family planning services were available (accounting for both regional and family characteristics potentially correlated with birth spacing). They find that lifetime exposure to family planning is associated with a 7% gain in child height and a 12% gain in child weight.

Beyond child health, family planning may benefit children in other ways throughout their lifetime, too – by increasing parents' investments in their education, for example (Becker, 1991). Evidence on the direct relationship between family planning programs and children's educational attainment is again thin, however, and limited to long-term studies of the Matlab experiment. Foster and Roy (1997) report that the Matlab treatment increased both girls' and boys' years of completed schooling (by 6–15% and 5–12%, respectively), an effect they link to reductions in sibship size. Joshi and Schultz (2007) find that relative to their peers in control villages, gains in educational attainment of 0.5 standard deviations persisted among boys (but not girls) in treatment villages.

Finally, a study of Romania's 1966 ban of abortion and family planning services compares cohorts born just after the ban (which include additional 'unwanted' children) with cohorts born just before it (Pop-Eleches, 2006). Controlling for family characteristics, children born after the ban were less likely to complete either high school or college (by 1.7% and 1.4%, respectively) and were instead 2.1% more likely to complete a lower-return vocational degree. This article attributes these changes in educational outcomes not only to the 'wantedness' of children, but also to crowding in schools among post-ban birth cohorts (the role of sibship size is not explicitly studied) (Pop-Eleches, 2006).

Conclusion

This article reviews empirical studies of family planning programs in developing countries, focusing on fertility and on the health and socioeconomic welfare of women and children. Because the family planning literature is vast, we used an informal approach akin to the 'systematic review' methodology in the biomedical sciences in an effort both to be comprehensive and to explicitly define our focus.

Pooling across studies, we propose several generalizations about family planning program effects. First, we find that program effects on fertility vary between 5% and 35% fewer children ever born and 5–7% longer birth spacing (see **Table 1** for a summary). Estimates from the famous Matlab experiment generally fall in the upper-end of this range – but we note that the experimental intervention is likely too intensive to be replicated on large scale, limiting the generalizability of its results – and they also presumably reflect reductions attributable to other health services bundled into the experimental treatment. Long-term studies of real-world programs yield more modest effect sizes, implying that, in practice, family planning programs may only explain about 8% of fertility decline in real-world settings. Overall, it is difficult to argue that family planning programs alone explain a large share of the fertility decline in developing countries over the past half century. Demand-side factors may play a more important role (Gertler and Molyneaux, 1994; Pritchett, 1994).

Second, we find evidence that family planning programs may have quantitatively modest – but practically meaningful – effects on the socioeconomic welfare of individuals and families. Excluding studies of family planning programs that bundle maternal and child health services into their service packages, there is little evidence about program effects on maternal and child health outcomes. However, long-term studies of socioeconomic outcomes suggest that family planning programs may raise educational attainment among

Table 1 Estimates of the effect of family planning programs of fertility outcomes.

Country	*Study period*	*Fertility measure*	*Marginal or incremental effect size*	*Relative effect size*	*Background fertility change during study period*	*Percent change explained*	*Citation*	*Notes*
Bangladesh	1974–80	General fertility rate	1.8	25%			Phillips et al., 1982	
Bangladesh	1967–90	Children 0–8	0.41	25%	25%		Foster and Roy, 1997	
Bangladesh	1974–96	Children ever born	1–1.5	15%			Joshi and Schultz, 2007	
Bangladesh	1974–96	Lifetime fertility	0.5	13%	40%	33%	Sinha, 2005	Calculated as the difference in lifetime fertility among women in treatment areas before and after treatment (7.21 vs 4.29)
Bangladesh	1974–96	Child to woman ratio	0.12	17%	46%	37%	Joshi and Schultz, 2007	Roughly calculated as the average change in fertility/1974 fertility level
Bangladesh	1974–96	Children ever born	1	23%			Joshi and Schultz, 2013	Calculated as the marginal change in children ever born/ overall sample mean children ever born
Colombia	1965–93	Children ever born	0.25–0.33	5%	51%	6-7%	Miller, 2010	
Ethiopia	2003–06	Total births during study period	–	–	–	–	Desai and Tarozzi, 2011	Results on total births during the 3-year study period are mixed, and in some cases point estimates are positive.
Ethiopia	1990–2005	Children ever born	0–0.9	0–20%			Portner et al., 2011	Effect size varies by educational attainment with effects concentrated among uneducated mothers
Ghana	1996–2003	Total fertility rate	1	15%			Debpuur et al., 2002, Phillips et al., 2006	
Ghana	1995–2010	Total fertility rate	0.42	42%			Phillips et al., 2012	
Indonesia	1970–93	Children ever born	0.9	18%			Angeles et al., 2005a	
Indonesia	1982–87	Quarterly birth hazard	0.07	1.8%	23%	4-8%	Gertler and Molyneaux, 1994	Calculated roughly, using overall 1980–85 fertility declines (declines between 1982 and 1987 not given)
Indonesia	1985–94	Quarterly birth hazard	0.03–0.06				Molyneaux and Gertler, 2000	
Iran	1986–96	Child to woman ratio	0.04–0.08	4–8%	46%	8–20%	Salehi-Isfahani et al., 2010	Calculated using the overall mean child to woman ratio in 1986 (0.95) and 1996 (0.51)
Iran	1970–2004	Children ever born	0.63–0.99	18–28%			Modrek and Ghobadi, 2011	Calculated roughly using overall mean children ever born
Iran	1970–2000	Yearly birth hazard	0.02–0.05				Hashemi and Salehi-Isfahani, 2013	Marginal effect size observed for higher parity births
Kenya	2005–09	Incident pregnancy	–	–	–	–	Kosgei et al., 2011	
Peru	1972–91	Children ever born	0.93–1.3	25–35%			Angeles et al., 2005b	Marginal effect size varies depending on educational attainment
Romania	1988–92	Yearly birth hazard	0.07				Pop-Eleches, 2010	
Romania	1988–92	Total fertility rate	0.39–1.1	28–34%			Pop-Eleches, 2010	Marginal effect size varies depending on educational attainment
Tanzania	1970–91	Children ever born		10–20%			Angeles et al., 1998	

Note: Column 4 reports the change in fertility associated with a one unit change in the relevant measure of family planning program, Column 5 gives the effect size relative to fertility level at baseline, Column 6 reports the overall change in fertility observed during the period of study, and Column 7 reports the implied percent of the overall fertility decline explained by family planning.

women (by 1–30%) and among children (by 5–18%). Although socioeconomic effects at the bottom end of these ranges may seem small, we note that they are not dissimilar in magnitude to gains associated with programs explicitly aiming to boost educational attainment.

Finally, we conclude by highlighting the considerable heterogeneity in the magnitude of program effects in the family planning literature and emphasize the importance of further work to explain them.

Family Planning Programs: Feminist Perspectives

Carmen Barroso, International Planned Parenthood Federation/Western Hemisphere Region, New York, NY, USA

Abstract

Since the 1960s, governments and private organizations implemented family planning programs, largely driven by fears of rapid population growth. By the 1990s, the rationale for these programs shifted to the human right to autonomy in sexuality and reproduction. With the 20th anniversary of the United Nations International Conference on Population and Development Programme of Action approaching, this article examines the feminist critique of population programs that led to this historic shift. It examines gaps that remain in the implementation of the Programme of Action, and emerging issues – including youth sexual rights – that feminists are prioritizing as key areas for population and development policies and programs.

Population Paradigms

Since the 1960s and even earlier in some cases, governments and private organizations in many poorer countries have developed and implemented family planning programs. By 1985, 37 governments had established national family planning programs, and an additional 33 countries had significant nongovernmental programs with the direct or indirect support of governments (Bongaarts et al., 1990). These efforts were largely driven by fears of rapid population growth, and the reduction of fertility was their highest priority. By the 1990s, however, critics of these programs succeeded in causing, what many have called, a revolution in the rationale for family planning programs. The human rights to autonomy in matters of sexuality and reproduction was proposed by feminists from the global north and south as the cornerstone for these efforts. As a result of this critique, 179 countries agreed to a new approach to population policies and family planning programs at the United Nations International Conference on Population and Development (ICPD), held in Cairo in 1994.

Family Planning Programs and the Erstwhile Population Approach

To fully understand the significance of the Cairo accord and the influence feminist thinking had on it, it is necessary to look at the philosophies and practices it replaced. The 1960s, with the advent of new contraceptive technologies and an increase in fears of a population explosion, saw a significant increase in support for family programs in both industrialized and developing nations. In 1967, the United Nations Fund for Population Activities (later renamed the United Nations Population Fund) was established to support population and family planning programs. At the UN population conference in Bucharest in 1974, many policy makers – mainly from Northern nations – viewed unchecked population growth as the root cause of poverty, environmental degradation, and social unrest. Many developing countries resisted this line of thinking, suggesting instead that economic development was a more straightforward solution to societal ills than family planning. While women's rights and empowerment gained some attention, they were not seen to be central arguments for family planning. Meanwhile, on the ground, family planning programs continued, largely unaffected by the debate at the international forum (Demeny, 1985).

At the 1984 International Conference on Population in Mexico City, demographic concerns continued to be the driving force in discussions. However, in a reversal of its previous policy, the powerful US delegation now asserted that population growth had a neutral, not harmful, effect on economic development. Furthermore, antiabortion politics gained center stage as the US launched an attack on abortion rights (Demeny, 1985). Still, family planning programs on the ground continued to be guided by demographic goals and to use mechanistic measures such as reaching target numbers of 'contraceptive acceptors.' The principal goal driving these programs was the distribution of contraception, chiefly to married women. Perhaps more accurately called population programs than family planning programs, these efforts usually did not address other health needs, even reproductive health needs.

The Feminist Critique of Population and Family Planning

As these programs proliferated throughout the 1970s and 1980s, women around the world began focusing on the negative effects of family planning programs that were based on demographics. While not denying the benefits of family planning, feminists rejected the depiction of women as targets of programs designed to limit births (Pitanguy, 1995). The feminist critique concentrated on several aspects of program practices, including their low quality, the vulnerability of women to coercion, and their sole concentration on fertility regulation to the exclusion of other women's health needs.

The vulnerability to coercion was a major element of the feminist critique. In some countries, health care providers were under pressure to achieve targets or be subject to penalties, and workers pressed people into accepting contraception or sterilization against their will. With the success of family planning programs measured in terms of numbers of acceptors, some agencies and governments devised incentive and disincentive schemes to induce couples to participate in family planning

 http://dx.doi.org/10.1016/B978-0-08-097086-8.31030-3

programs. For some time, there was a debate about the fine line separating incentives from coercion. Feminists argued that, while milder than sheer force, the incentive practice was coercive, and that incentives were aimed primarily at the poor, for whom an economic inducement could be a vital necessity rather than a free choice (Hartmann, 1995). The Cairo Programme of Action later renounced incentives.

Furthermore, women – and women were the objects of these campaigns in much greater numbers than men – were given little contraceptive choice. The focus was on sterilization or other modern, provider-controlled methods of contraception such as the injectable Depo-Provera. The risks of these methods, feminists argued, were largely ignored and even exacerbated as a result of poor screening procedures and the lack of follow-up examinations. Safer methods, such as the condom and diaphragm, were neglected, even though barrier methods have the ability to help prevent the spread of sexually transmitted infections. Indeed, apart from fertility regulation, family planning programs provided little else in the way of services. Furthermore, male contraceptive methods were ignored in the research sphere and male participation was neglected in family planning programs, except for sterilization campaigns in some countries (Dixon-Mueller, 1993).

Feminists insisted that reproductive health programs be comprehensive in nature with family planning being only one item in a wide range of women's reproductive health needs. Other reproductive health services included skilled care during pregnancy; delivery and postpartum care; prevention of infertility; counseling for sexual dysfunction; safe abortion; prevention and management of sexually transmitted infections; reproductive tract infections and reproductive system cancers; and treatment of postmenopausal health problems (HERA, n.d.).

Furthermore, feminists demanded that women's health advocates should be represented at all levels of policy and decision-making. They also maintained that men's responsibilities in the reproductive realm should not be ignored (Women's Declaration on Population Policies, 1992).

Perhaps most central to the feminist critique is the assertion that women have the ability to make appropriate reproductive choices. In the feminist view, reproductive choices belong at the individual level, not with the health practitioner and especially not with the state. Noncoercive family planning programs aim to prevent unwanted pregnancies – as defined by couples, not by the government or other outside parties – through the provision of competent services that respect dignity and privacy. The essence of the feminists' perspective is the view that reproductive rights are human rights.

Another fundamental premise of the feminist perspective on family planning programs sees women's empowerment and equality as a desirable goal in its own right, rather than a means to a demographic end. Feminists also emphasize men's responsibilities in sexual and reproductive matters (García-Moreno and Claro, 1994).

Articulating these views, women in many countries around the globe began advocating for a wholesale transformation of the approach to population policies and family planning programs. By the time of the 1994 United Nations International Conference on Population and Development (ICPD), an international women's health movement was organized and had developed the expertise and the professional skills needed to influence policy makers and incite the transformation of global population and family planning programs (Klugman, 2000). "The Cairo Programme of Action sums up the agenda of priorities which women from all over the world, through their leadership networks, built gradually during the years of preparation for the conference" (Berquó, 1997).

The Cairo Programme of Action and the 'Feminist Imprint'

The Cairo conference ushered in a new era of population policy and family planning programming. Its resulting Programme of Action reflects a clear 'feminist imprint' (Petchesky, 1995). The conference document presents a new perspective, in which high rates of population growth are understood as an interdependent and aggravating factor – rather than the cause – of problems such as poverty and environmental degradation. Even more critically, it places women's well-being at the center of population policy, and points to the human rights of individuals to determine and plan family size. Unlike documents from previous population conferences, the ICPD Programme of Action includes chapters on 'Reproductive Rights and Reproductive Health,' and 'Gender Equality, Equity and the Empowerment of Women.'

Echoing the feminist critique, the comprehensive nature of reproductive health is elucidated in Section 7.2 of the Programme of Action, as follows:

> Reproductive health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity, in all matters relating to the reproductive system and to its functions and processes. Reproductive health therefore implies that people are able to have a satisfying and safe sex life and that they have the capability to reproduce and the freedom to decide if, when and how often to do so. Implicit in this last condition are the right of men and women to be informed and to have access to safe, effective, affordable and acceptable methods of family planning of their choice, as well as other methods of their choice for regulation of fertility which are not against the law, and the right of access to appropriate health-care services that will enable women to go safely through pregnancy and childbirth and provide couples with the best chance of having a healthy infant.

While previous population conferences had viewed women's development as a tool for achieving lowered fertility rates, the Cairo Programme of Action framed women's empowerment as a goal worthy in its own right. 'The empowerment and autonomy of women,' the agreement reads, "and the improvement of their political, social, economic and health status is a highly important end in itself" (*Programme of Action*: 4.1). In another clear echo of the feminist critique, the document goes far in its call for gender equality (*Programme of Action*: 4.1):

> The power relations that impede women's attainment of healthy and fulfilling lives operate at many levels of society, from the most personal to the highly public. Achieving change requires policy and programme actions that will improve women's access to secure

livelihoods and economic resources, alleviate their extreme responsibilities with regard to housework, remove legal impediments to their participation in public life, and raise social awareness through effective programmes of education and mass communication.

Critiquing the Critique

The feminist critique has its detractors and the outcome of the Cairo Conference was not universally applauded. Vocal critics were mainly religious fundamentalists, especially the leadership of the Roman Catholic Church (Shannon, 1994). A much quieter reaction was registered among some demographers and others whose concerns about high rates of population growth led to their dismay at what they saw as the dismantling of population policies (Dixon-Mueller and Germain, 2000). For example, Malcom Potts maintained that the "flaw in the Cairo process was to move from a well-tested middle ground of supplying family planning to adopting a much broader agenda" (Potts, 1995). Jason Finkle and Alison McIntosh claimed that women's groups 'co-opted' the ICPD. The conference, they maintained, was "not a step forward for the population movement, which for many years has given primacy to efforts to limit population growth" (Finkle and McIntosh, 1996).

Even some supporters of the reproductive health paradigm adopted in Cairo found some faults in its processes and outcomes. In a review of responses "that tend to temper the initial feeling of euphoria surrounding the triumph of the feminist agenda," Huda Zurayk writes that while a large number of women from Third World countries were present in the ICPD process, "the strings were definitely being pulled by the well-organized Western feminist groups" (Zurayk, 1997). Others, however, point to the significant contribution of women from the Global South – particularly women from Brazil, India, Egypt, Nigeria, Mexico, and South Africa – to the ICPD agreement.

Beyond Cairo: The Feminist Critique Moves Forward

After the Cairo Conference, the feminist critique expanded to include a vision of policies, governing not only family planning programs but also the broader panoply of issues related to reproduction and sexuality. One year after the ICPD, in 1995, the United Nations held another major international conference in Beijing focusing on women's rights. Again the ensuing conference document – the Beijing Platform for Action – reflected feminist input. While the Platform did not explicitly use the phrase 'sexual rights,' the agreement nonetheless endorsed the basic tenets of such rights, and placed them within a human rights framework. "The human rights of women include their right to have control over and decide freely and responsibly on matters related to their sexuality, including sexual and reproductive health, free of coercion, discrimination and violence," reads paragraph 96 of the *Platform for Action*.

There is little question that feminist analysis has had significant influence on policy worldwide, principally through the actions of women's nongovernmental organizations. Feminist scholars have pressed for a similar impact on the discipline of demography, where gender issues have remained marginal. While ideological resistance presents a considerable obstacle, "intellectually, the incorporation of gender issues in demography promises to enhance the science by offering a deeper understanding of social process and the application of multilevel methodologies" (Presser, 2000).

As the 20th anniversary of the ICPD approaches, feminists are calling attention to the glaring gaps and inequalities that remain from the uneven implementation of the Cairo agenda, and from issues that were not fully addressed in Cairo. Four themes have been the focus of the feminist critique of late: sexual rights, unsafe abortion, comprehensive sexuality education, and government accountability. The one that is getting more traction in international fora is the sexual rights of youth, which also encompasses the right to sexuality education.

Today's generation of youth make up the largest cohort of young people ever, and addressing their needs is an increasingly urgent concern of family planning agencies. The unmet need for contraception among adolescents aged 10–19 is more than twice that of adult women (Guttmacher, 2010), while nearly a fifth of young women in developing countries become pregnant before they turn 18 (UNFPA, 2013). Another egregious violation of young women's sexual rights is the practice of early and forced marriage. In developing countries, some 16% of girls marry before they are 18 years old, and they are often pressured to conceive immediately, with harmful implications for both the mother and baby (UNFPA, 2013).

The Cairo Programme of Action (Paragraph 7.3) called upon governments to commit "to the promotion of mutually respectful and equitable gender relations and particularly to meeting the educational and service needs of adolescents to enable them to deal in a positive and responsible way with their sexuality." Yet young people still face formidable social and psychological barriers to the exercise of a healthy and pleasurable sexuality. Some of these barriers are common to those affecting all people especially those living in poverty, such as lack of sufficient resources for reproductive health programs and persistent opposition from conservative sources deeply opposed to reproductive autonomy. In fact restrictions to young people's access to services have been a major rallying cry of conservative forces, which seem to have lost ground on the power they exerted in controlling people's behaviors in their daily lives in many parts of the world, but are very active exerting political power both at national and international levels.

The family planning programs are now aware of the need to cater to young people, but all too often, reproductive health programs for youth are focused primarily on preventing teen pregnancy and hence are subject to a similar feminist critique to that which was applied against early family planning programs. These programs for youth see young people narrowly as mere contraceptive users, rather than recognizing them as sexual beings with sexual rights. As a result, young people end up alienated from information and services, and hence do not have the resources they need to fully exercise their rights.

A further impediment to young people's rights is the proliferation of legislation establishing high age of consent, below which any sexual relation is considered statutory rape,

and laws requiring parental consent for minors to access a range of sexual and reproductive health services, including information, counseling, contraception, and abortion. While these laws are intended to protect children, they are actually not very effective in preventing the abuse of minors or fostering dialogue between parents and adolescents. In fact, these laws are counterproductive because they impede adolescents' access to the contraceptive technologies they need to safely and responsibly exercise their sexuality. They also infringe upon young people's autonomy. Article 5 of the United Nations Convention on the Rights of the Child establishes that, as children grow older, their evolving capacity for decision-making must be taken into account, increasingly allowing minors to exercise their rights on their own behalf according to their capacity (United Nations, 1989).

As the development community prepares to negotiate a new post-2015 global development agenda, young people themselves are taking the position of leadership exercised by feminists in 1994 in their call for the primacy of a rights perspective. At the 2012 Global Youth Forum in Bali, some 3000 youth participated in drafting a declaration that echoes the feminist agenda in Cairo and takes it one step further. For example, the declaration's text on sexual rights states:

> Governments must fund and develop, in equal partnership with young people and health care providers, policies, laws, and programs that recognize, promote, and protect young peoples' sexual rights as human rights. This must be developed in accordance with the principles of human rights, non-discrimination, respect, equality and inclusivity, with a gendered, multicultural and secular approach … Cultural and religious barriers such as parental and spousal consent, and early and forced marriages, should never prevent access to family planning, safe and legal abortion, and other reproductive health services – recognizing that young people have autonomy over their own bodies, pleasures, and desires.
>
> UNFPA, 2012.

One obstacle to integrating a rights perspective into the development agenda is that international health donors have become increasingly focused on measurable results. In principle, this shift is a positive one. The problem is the narrow definition of results prevailing in this new paradigm. The standard indicator used to measure the success of family planning programs is the number of years a couple will be protected against unwanted pregnancies. This indicator encourages the promotion of long-acting contraceptives, such as the intrauterine device and implants. Many women do want to use long-acting contraceptives, and therefore increasing access to these methods is a positive move. However, promoting them to the exclusion of other methods is problematic in that they do not offer protection against sexually transmitted infections, including HIV, and they may be less appropriate for women who have sporadic sexual relations or multiple partners, as well as women who may be unknowingly exposed to sexually transmitted infections from their spouse or partner. Furthermore, these long-acting methods have significance for many women's rights advocates who recall a bygone era when population growth was seen as the major driver of economic and social ills, and when family planning programs driven by numerical targets related to contraceptive use led to the neglect of proper health education and informed consent, particularly for women and men in developing countries.

This concern was at the root of the feminist reaction to the London Family Planning Summit, which was cohosted by the Bill and Melinda Gates Foundation and the UK Department for International Development in 2012. The purpose of the Summit was to draw attention to the family planning agenda, which had become a neglected area of health and development both in terms of funding and research. The Summit was successful in gaining both political and economic support for reducing the unmet need for family planning. Feminists and sexual and reproductive health and rights advocates were very vocal in raising concerns in the run up to the event, when the narrow focus on family planning seemed to diminish the hard-won gains of Cairo to place family planning within the context of women's broader, sexual, and reproductive health needs and rights. Furthermore, the Summit was criticized for its exclusion of the issue of unsafe abortion, and exclusive focus on numerical targets for access to contraception (Guttmacher, 2012). If the only measure of success is new contraceptive users, feminists and rights advocates argued, providers would feel pressured to meet those targets without regard for rights. In particular, the government of India, one of the countries that made commitments at the Summit, drew heavy criticism given the persistent use of incentives for sterilization quotas, health workers are still expected to fill in many states, in spite of the abolition of centralized targets soon after the Cairo conference (Human Rights Watch, 2012). The organizers of the Summit were quick to respond to these criticisms and included repeated references to the importance of women's rights, and rousing speeches were made pledging to give women and girls the power to decide. FP 2020 was created to follow-up the commitments of the Summit. Its first report, launched in November of 2013, mentions the development of a framework to measure and report on the autonomy, equity and human rights-based dimensions of family planning programs but it is still unclear how this will be implemented or measured (Family Planning, 2020).

Family Policy

Mary Daly, University of Oxford, Oxford, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Family policy, at its most developed in Europe, refers to state policies oriented to the welfare of children and the support of family as an institution or way of life. Most widely, family polices concern themselves with demographic matters, the financial and other resources available to families, gender equality, the links between family life and employment, and the role and significance of family as a social organization. The most common constituent elements of family policy consist of cash benefits for families with children, child care and early education services, and leaves from employment for family-related purposes. Family policy is characterized by great variation and, in the last decades, considerable reform.

Defining the Field

Family policy is not at all clear-cut as a field of social policy and there is no agreement on a definition. It is in fact a broad field – Gauthier (1999: 32) terms it a 'wide umbrella of policies.' As such, critical decisions are required about what to include and exclude. One way of approaching this is to think in terms of what society considers as family. From this perspective, families with children would be at the center of any definition of family policy. A societal understanding of family also suggests that family policies should encompass policies on the care of older people, given that in many societies this is seen to be the responsibility of families. However, if we take the stance of the state – which is the customary starting point for policy analysis – policies for older people are not widely regarded or made as family policies. They most often fall within the domains of health or pensions/retirement policy. One of the earliest definitions of family policy is that used by Kamerman and Kahn (1978). They defined it as deliberate governmental actions taken toward families with children. Both scholarship and policy have moved on from this, especially in recognizing that family policy is not limited to that which is focused specifically on family. While the focus more or less remains on families with children, it is now customary to consider as family policy a range of instruments that governments use to support, influence, and regulate behaviors and welfare in different types of families with children.

This contribution takes the broader route in several respects, especially in recognizing the context within which family policies are designed and operate. In this regard, I would emphasize two things. First, seeing the broader context means recognizing that family policy is implicated in organizing the interrelations among the family, state, and market. In other words, while it may appear to be micro and rather small scale, family policy is actually part of the governance of foundational matters relating to how the economy and society are organized. Second, it is important not to underestimate the complexity of family. Rather than a mere structure, families are constituted by sets of interrelationships and divisions, especially along gender and generational lines. So family policies are intimately involved in governing these and other considerations. In addition, understanding family as complex means that we cannot view it as a passive phenomenon on which state policies stamp their mark without any resistance. Rather, family has to be seen as a domain and sphere of activity in its own right, with its own dynamic, relationships, and interests.

In the analysis to follow with the main focus on Europe, attention is centered especially on the typical approaches and how these vary across countries, the drivers and political background, the types of policy instrument in place (cash benefits, tax allowances, leave, and services), the motives and objectives, financing and other arrangements, and general trends.

The History of Family Policy in Europe

Taking Europe as the canvas, one can, generalizing somewhat from Bahle (2009) and Daly (2010), identify two general contexts in the history of engagement between states, markets, and families. The first was of industrialization and nation-building wherein the state and political actors, from the late nineteenth century on, endeavored to respond to the needs generated by the shift from agricultural to industrial forms of production and economic organization. From a family policy perspective, the central intent here was the support of the working man and his family. With the male breadwinner family as the orienting image, early social and family policies linked closely to the idea of a family wage, and provided subsidies for both marriage and the 'dependants' of the breadwinner (Crouch, 1999). The dynamic in the second period, commencing in the 1970s, lay in the expansion of the service economy and, associated with this and other factors, the large-scale movement of women into the labor market. This turned the focus on a broader meaning of family support, one tied into the question of how family-related roles and functions could be reconfigured in order to enable economic and social reform. Gender politics sat alongside class politics as shaping influences in this period when services substituting for maternal caregiving and financial support for families grew rapidly, as did state interest in the early education and care of children.

There are many possible goals of family policy just as there are many interpretations of how family policy affects family life and vice versa. As Ferrarini (2006: 1) points out, when legislating for services or transfers policy makers modify the bundle of choices available to an individual and so delineate the

range of citizens' personal agency. In addition to individuals' behaviors around family life and employment, other primary 'targets' for intervention on the part of family policy include the relational and caring aspects of family life and the functioning of family as a social and economic institution. Kaufmann (2002: 426–428) identified the following classic motivations for family policy within and across countries:

- the natalist motive – the importance of keeping the birth-rate up and managing demographic change;
- the economic motive – the improvement of the stock of human capital and bolstering the family's contribution to economic functioning;
- the socioeconomic motive – balancing of employment (self-sufficiency) and support for the family;
- the societal motive – maintaining the significance of the family as a form of social capital and a source of social stability;
- the sociopolitical motive – compensating for the costs of having families;
- the institutional motive – to protect the family as a valued institution;
- the gender equality motive – to affect the distribution of resources and roles between women and men; and
- the children's welfare motive – to ensure that children are reared with sufficient resources and to improve their welfare through a range of services and provisions.

Family policies were slow to develop. It is generally agreed that state responsibility for families developed later than other areas of social policy (Gauthier, 1996). Among the first family policies were those offering financial assistance to families with children, either through subsidies to wages or through cash allowances for children (known as 'child benefits'). These dated from the 1940s in many countries (and earlier in some) but only in the late 1960s did countries first start to expand family and child care services (e.g., Denmark, Sweden, and later Norway, Finland, Belgium, and France) and other countries universalize child benefits (e.g., Germany, Austria, and Luxembourg). Any slowness was partly due to the difficulty of making policy for such a value-laden sphere as family – which is generally seen as private – and also because there were few actors pushing for family policy and, indeed, a number actively pushing against it (such as in some countries the Catholic Church, which wanted to keep the family as a sphere where Catholic moral influence would prevail).

A range of different actors and providers are involved in family policy. These include, in addition to the public authorities (national, regional, and local), the nonprofit and voluntary sectors (nongovernmental organizations). In some countries, the latter (including church-related bodies) are major providers of family-related services and in others such as France they have played a big role in politicizing family policy. Joining these in service provision are firms and enterprises that have become more important over time.

Different Types of Family Policy Approaches

A comparative approach is almost essential for family policy because it varies so widely. One of the big contributions of comparative welfare state research has been to demonstrate that family policy is part of a much broader set of arrangements and 'settlements' (on the part of powerful actors in society especially) around the functioning of economy and society (Ferrarini, 2006; Hantrais, 2004). This means that, while family policy usually arises to meet needs or solve 'problems,' it is influenced by ideological and normative positions and is almost always tied to a particular arrangement of state, market, polity, and society.

The strength of particular underlying motivations and the diversity of national philosophical orientations toward the family has led to a number of distinct models of family–state–market relations in Europe historically (Daly, 2010; Hantrais, 2004).

A first approach, typified by (West) Germany and Austria, developed in a context where family as an institution had high social value and constituted a legitimate ground for political action. Indeed, the claims of the family were elevated and placed above those of other institutions or social categories by the principle of subsidiarity. The latter decrees that, while the purpose of state support is to enhance family well-being and functioning, such state action should not undermine the autonomy of the family. Social policy in this mold idealized and bolstered the family as an essential source of stability. There was a strong preference for the male breadwinner/female homemaker family model. The mother at home symbolized the appropriate moral order. This, together with the widespread belief that young children should be cared at home, made for a strong gender division of labor. However, it was a widely held belief, and one slow to recede, that families should be financially supported with child rearing and the cost burden of children shared by the society. Hence, this model of the welfare state tended to organize its support of families in the form of income supplements rather than services that tied in with the ideology of mother as carer.

The second classical model was egalitarian, wherein the objective of state policies was to support employment on the part of both female and male parents; and in order to do so, families had to be given access to high-quality child care and other services. This model, found in the Scandinavian countries, did not operate with a strong concept of family as a collective or even separate institution but was much more individualistic (Ellingsaeter and Leira, 2006). Women's role and identity as workers was written into the institutions of state and market as was the principle of individual independence and autonomy. On the one hand women were enabled to be workers and on the other the service-intensive state more or less took over the care of children beyond the toddler stage. Family membership might be a source of emotional stability and identity but family as a privileged social unit was much less supported as compared with other parts of Europe. As a result, this type of welfare state model tended to make public what in other countries is placed beyond the reach of the state. Service provision for families was widespread and children (as well as other members of society) had extensive social rights.

Finally, there are countries such as the United Kingdom (and other liberal countries such as Australia and Canada) where, instead of generic family support, policy draws mainly from an antipoverty and economic functioning orientation.

State intervention in family lacked legitimacy in these countries, apart from preventing or managing social ills such as poverty and family malfunction. The individualism of these cultures and the value placed on financial independence and self-sufficiency, on the part of both individuals and families, tended to veto state intervention for the purposes of generic family support. This rendered family policy relatively underdeveloped; where it existed it was oriented mainly to the prevention of poverty and 'crises' occasioned by familial 'dysfunction.' Policy stayed well away from the social recognition of the family as practiced by French and German policies (O'Connor et al., 1999).

Other models also exist. For example, in the Mediterranean countries, the state tended to desist from putting in place anything other than rudimentary support for families. Without much in the way of cash benefits or tax allowances for their children, families tend to be left to their own devices, which among other things makes for a vibrant flow of support and considerable dependence across the generations.

While these different models might appear like historical artifacts nowadays, in fact the originating philosophy and historical pattern of family policy tend to endure. Hence, new developments are shaped by a country's historical framing of the relationship between family and the state on the one hand and family and economy/society on the other. That said, there is considerable reform and powerful influences are pushing for convergence across countries.

Expenditures on Family Policy

In 2009, the Organisation for Economic Co-operation and Development (OECD) countries on average spent 2.6% of their gross domestic product (GDP) on family policy (OECD Family Database). Across the OECD area, the total public expenditure on family policy ranged from less than 1% to about 4% of GDP. Expenditure on cash benefits was about 1.5% in the OECD and EU countries. However, countries organize their spending quite differently. For example, Denmark and Sweden put an emphasis on parental leave compensation and therefore exhibit only average spending on family allowances despite an overall high expenditure on total cash benefits. The majority of countries spend a higher proportion on cash benefits than on services or tax benefits. Exceptions include Chile, Denmark, France, Iceland, Israel, Italy, Korea, Mexico, Netherlands, Norway, Spain, Sweden, and the United States, where spending on services is the same or higher. Also, the proportion spent on tax breaks toward family is of considerable size in Belgium, the Czech Republic, France, Germany, Japan, the Netherlands, Slovenia, and the United States (more than 0.5% of GDP).

Main Constituents of Family Policy

As mentioned, family policy in most countries has mainly concerned itself with supporting families with children and child-rearing. Raising children incurs both direct and indirect costs, the former arising from the additional costs involved with children and the latter mainly from income foregone from employment because of childbearing and child-minding. Welfare states have long compensated for the former but they were much slower to take on the latter, although moves toward gender equality and concerns about work–family balance have opened policy makers' eyes to indirect costs and family members' preferences. Given the variety of innovations being introduced in family policy, the discussion that follows considers only the main elements of family policy, namely, child benefits, early education and child care services, leaves from employment, and provision by employers or enterprises.

Child Benefits

Historically across Europe child benefits or family allowances were the main pillar of family policy. Designed to assist families with some of the costs of raising children, they date mainly from the period around World War II. At the time of their introduction and subsequently, they represented a truly innovative form of social right since they tended to have no conditions attached to receipt (Montanari, 2000: 309). Usually paid until the child reaches school-leaving age, these allowances exist in every country of the EU today, although their levels vary considerably and they are not universally available to all families. While most countries grant family allowances without income-testing, nine EU member states means-test them (Blum and Rille-Pfeiffer, 2010: 11). Means-testing of these allowances tends to be characteristic of the Mediterranean and postsocialist countries, although the current Conservative/Liberal government in the United Kingdom has also introduced reforms that target the benefit by family income. When countries target, they tend to do so usually on the basis of family income, although some countries also target by the age of the child and number of children. Child benefits are usually funded from general taxation revenues and in this and other ways are an expression of societal support for people who are raising children.

At average earnings, the family benefit package of a family in the OECD countries is worth on average about 10% of the average wage (OECD Family Database). In many countries, the size of the package depends on earnings. In some countries, the family benefit package differs sharply by family size. On average, the benefit for the third child is about 2 percentage points (of an average wage) higher than that for the first child (Lohmann et al., 2009: 54). The situation for single parents in terms of the family benefits package is not advantageous in all countries. Comparing the family benefit packages by family type shows that in Belgium, Sweden, and the Slovak Republic, taxes and benefits place single parents in a less advantageous position as compared with couples without children (Lohmann et al., 2009: 54). In comparison to couples with children, the benefits for single parents are the same or lower in a large number of countries, with some notable exceptions like Austria and Norway. On average, the family benefit packages of single parents are about the same as those of couples with children at the same wage level in the OECD countries (−0.2) and are smaller on average in the EU countries (Lohmann et al., 2009: 54).

Early Childhood Education and Care

This area of provision has become much more important in recent years, associated with both the growth of children's

rights and countries' concerns about the educational performance and general behavior and achievements of their populations. The provision of day care for children is the classic policy response here. However, looking across countries, this is a differentiated phenomenon as some countries view it as care for children, whereas others regard it in terms of education and early learning (Scheiwe and Willekens, 2009). Typically, ECEC focuses on children under compulsory school age and refers to services provided outside the home (in nursery or crèche settings, for example). As Lohmann et al. (2009: 42) point out, the term ECEC originates from the term 'early childhood development,' which emphasizes a holistic approach to the child's physical, emotional, social, and cognitive development. Another commonly used term, 'early childhood education' is favored by educational authorities, who wish to emphasize the learning aspect, and is used especially in the United States (Scheiwe and Willekens, 2009). ECEC services also differ in terms of which ministry they are under; in some countries it is the ministry of education, whereas in others it is the welfare ministry.

The origins and background of ECEC differ fundamentally (in line with the models outlined earlier). In some countries, such as the Nordic countries, ECEC arrangements were initially set up to provide care for the entire age group from birth to compulsory school age during the times when parents were at work. In other countries, such as Germany, ECEC provisions originated in the objective of offering educational or pedagogical services to children aged 3 years and over before they entered primary school. In still other countries such as the United Kingdom, the goal was to offer care and early education services for children from disadvantaged backgrounds. While Lohmann et al. (2009) see the influence of encouraging maternal employment in the services existing today, they also point out that the institutional design of services for young children still in many ways reflects fundamental differences in originating objectives.

When compared across countries, there are other key lines of variation in ECEC policy as well. The main ones include whether there is a legal entitlement, the age range of the children covered, the level of enrollment or service availability, the cost or affordability, and the opening hours (see Plantenga and Remery, 2009). These will be briefly discussed in turn.

Some countries have introduced legal entitlements to day care. Statutory entitlements to child care have been enacted in a number of countries (e.g., Finland, Sweden, Denmark, Norway, Germany, and the United Kingdom) while in Austria, Cyprus, Hungary, Luxembourg, and Poland, the last preschool year has been made compulsory. Most of these guarantee day care services to children over the age of 3 years, but some of the Nordic countries also provide these services to children under age 3 years. As Lohmann et al. (2009: 43) point out, though, a guarantee of service provision does not mean that adequate services are actually available; there may, for example, be long waiting lists to get into day care programs. Most European (and many other) countries saw enormous growth in day care provision in the last 20 years. Among the EU countries, this was prioritized as an area for growth, not least because the European Union set targets for child care provision in 2002; known as the Barcelona targets, these set a target that 33% of the 0- to 2-year-old cohort should be in child care and 90% of those aged between 3 and 6 years by 2010. Child care for older children is more accepted than that for younger children. It is common for countries to differentiate between services for children aged 0–2 years and those between the age of 3 years and school age. Cultural norms around motherhood and parenthood affect the demand for day care and also to some extent the supply. Other factors that have an impact are the levels of employment and unemployment and how these are distributed between women and men.

On the basis of figures for 2008, overall enrollment at a relevant facility is 30% on average for children aged 0–2 years in the OECD and 28.2% in the EU-27 countries (OECD Family Database Chart PF 2.3.A and Table PF 3.2.A). For children aged between 3 and 5 years, on average 77.3% in the OECD area and 81.8% in the EU-27 are enrolled in some kind of care or educational service (Lohmann et al., 2009). Enrollment rates vary widely although the Scandinavian countries tend generally to have the highest levels of enrollment.

In addition to enrollment rates, another source of variation in regard to funding in turn affects the costs to parents. Public funding for ECEC for 0- to 2-year-olds covers on average 82% of total costs in the European Union and in the OECD countries alike (Lohmann et al., 2009). The public share is highest in Ireland (100%) and lowest in the Netherlands (64.5%). For older children, aged 3–6 years, the European Union and the OECD average public funding covers some 94% of the cost.

The average opening hours for facilities for children aged between 0 and 2 years vary from 7 h per day (Spain) to 11.5 h (in Sweden), with an EU and OECD average of 9.3 h a day (Lohmann et al., 2009). For older children, much provision is offered part-time, and opening hours for 3- to 6-year-olds vary from 4 h per day (Greece and Ireland) to 11.5 h (Sweden).

The widespread trend of child care expansion is in some places accompanied by what might be thought of as a counter move: the introduction of a choice-oriented home care allowances. Finland was a pioneer in this regard when in 1985 it instituted a policy that entitled any parent who stayed at home with their 1- to 3-year-old child to receive compensation from the government. A cash benefit for child care is available after the period of paid parental leave has run out and until the child reaches the age of three provided the child does not attend state subsidized child care. Norway introduced a similar provision in 1998. Other countries also are encouraging diversity and choice. France, for example, gives financial support to families to provide child care at home, either by the parent or through the employment of a home-based child care worker. Spain, too, has a benefit encouraging home care – families with three or more children can reduce social security contributions by 45%, if they hire a child minder or domestic worker (Daly, 2011).

Parental and Maternal/Paternal Leaves

Maternity leave is one of the oldest social security benefits, given that maternity has long been recognized as an income and health risk, especially when women are employed. The classic maternity leave – which dates in some parts of Europe from the end of the nineteenth century – was introduced so as to allow women a respite for some weeks prior to and after the child's birth. The leave typically guarantees a period away from employment during which the leave holder's employment

will be protected and also gives some income replacement for foregone wages during leave.

However, Europe is seeing innovation not so much in maternity leave as in other types of family-related leave. From the 1990s on parental leave has become more important. This is a job-protected term of leave provided to enable parents to care for their child, normally during the first year of life. The right to take leave is typically available to the mother and the father, who are usually left to decide between themselves how they will utilize and divide the leave. Sometimes, a certain period is set aside for the second parent.

Increasingly now, countries also offer paternal leave, which is job-protected leave provided to the employed father, normally to be taken near the time of childbirth in order for him to spend time with his newborn child and offer support to the mother and other children in the home. Typically it is of short duration – a number of weeks – and paid at a flat rate. The motivations for its introduction vary. It has been taken forward especially in the Nordic countries by instituting an individual, nontransferable right on the part of each parent to the leave. The so-called father's quota was pioneered in Norway in 1992 to encourage fathers to take child-related leave. Although it is not universal across the Nordic countries, it is regarded as a very important measure toward greater gender equality and improving father–child relationships.

In regard to leave length, the analysis by Lohmann et al. (2009) of provisions in the 38 most developed countries in the mid-2000s indicates that the average length of maternity leave in the EU countries is 17.7 weeks and in the OECD countries 16.1 weeks. Of the countries that provide paid paternity leave, the longest leave is available in Iceland (13 weeks) and the shortest in Austria, Greece, Ireland, Luxembourg, the Netherlands, and Spain, which each award less than 1 week of paid paternity leave. On average, fathers in the EU countries have 1.9 weeks of paid paternity leave available and in the OECD countries 2.8 weeks. Parental leave periods vary from 12 weeks (Belgium and Italy) to 156 weeks (Poland, France, the Czech Republic, and Slovakia), with an EU average of 82.4 weeks and an OECD average of 69.4 weeks.

Employer/Enterprise Provision

As Lohmann et al. (2009: 59) point out, new approaches to national family policy focus much more on employers than former policy approaches did. However some countries, such as the Netherlands, have a tradition of employer support for families and many of the Continental European countries have a history of providing wage subsidies for fathers.

These authors suggest that one can distinguish between sets of workplace practices that either are enforced by law on the national or subnational level or are agreed upon between unions and employers or within the firms themselves. At the firm level, four types of family-friendly working arrangements can be distinguished: flexible working arrangements, special leave arrangements, special child care arrangements, and other supportive arrangements (the framework was originally developed by Den Dulk, 2001).

With regard to flexible working arrangements, which are increasingly common (although this may be changed by the recession), the measures favored include part-time work, flexitime, telework, and a system that allows for banking or saving hours. The European Union played a role by stipulating the principle of nondiscrimination of part-time work in terms of working conditions in the EU part-time work directive 97/81/EC 21. Often part-time arrangements are settled at the level of the firm, but some countries have national legislation.

With regard to leave and child care arrangements, the measures provided at the firm level are often complementary to parental leave and child care provided on the national level. Thus, leave arrangements offered by employers are often provided for family reasons (e.g., sick child). Child care arrangements at the firm level may include workplace nurseries, contractually guaranteed slots in outside child care facilities, or financial assistance (for an overview, see Den Dulk, 2001). Other supportive measures offer possibilities such as work–family management training or employee counseling. However, the general consensus is that these services are not widespread among firms, and there are hardly any representative internationally comparable data on this (Lohmann et al., 2009: 60).

An Overview of General Trends

As we have seen, family policy has a number of different goals and is a dynamic area of policy within and across countries. Until relatively recently, governments were able to take for granted the existence of the traditional family, in terms of both its form and the gendered arrangements of earnings and care on the part of the husband/father and the wife/mother. However, during the last 20 or so years economic and family changes have become major drivers of policy change. Expenditure reflects this, with a spike in spending on family policy in most countries up to the recent recession (OECD, 2011). Spending on young children, and especially in relation to early child care services, was the main focus of growth.

Over time, one sees new emphases in policy and new rationales. While there is considerable variation in reforms being introduced, it is possible to identify a number of common trends.

1. There is a move toward a more diversified set of family supports wherein cash benefits sit alongside tax allowances, services, leave, and employment-based measures to comprise the typical family policy portfolio. So family policy is not just becoming more active, it is also becoming more diverse. This is true both within countries and across them. The field of family policy is broadening and deepening. Diversification is also seen in terms of the providers of services to families with an increased role for the private sector (especially for the profit sector and employers) and a reduced role for the public authorities as providers of services (although they continue to be major funders).
2. There is also a discernible move toward children's rights and a greater concern with children's early education, development, and well-being. The general concerns around children and childhood have led to both improved access for children to education and welfare services and the introduction of social and political rights for children (with a special emphasis on their right to participate in decisions that directly affect them). A notable development has been the growth and in some cases intensification of services oriented

to children's early development (e.g., ECEC, parenting support) and an increased focus on measures to combat poverty and disadvantage among children. As the OECD (2011: 66) puts it, policy is increasingly treating early childhood as a distinct period of life.

3. A further identifiable trend is toward a closer focusing of state support on parenthood and parenting. Law and policy today tend to emphasize parental or biological responsibilities over relations of marriage. The financial and care-related obligations of fathers are especially in focus. There is also a move away from a tax privileging of marriage and a tendency to grant nonmarried couples similar rights and responsibilities as married couples in regard to children.

Particular rationales underlie these and other developments. It seems to me that at the present time, two approaches are predominant. One is the social investment approach. While it has other defining emphases, scholars like Jane Jenson (2004) and Ruth Lister (2006) have read the focus on children and child-rearing as centripetal to a new welfare paradigm in Europe. This 'new' welfare architecture is oriented toward children and the reproduction of the labor force, viewing social expenditures as most justifiable when they lead to the accumulation of 'capital.' Childhood has become politicized and children a potential asset to be 'harvested' in the future.

A second rationale, more a policy aim than a worked out paradigm, is work–family reconciliation. The general intent here is to balance or 'reconcile' working with family life. This has had two main expressions in policy. On the one hand, employed parents are given increased incentives and support to take time off work to care for their children. Both parents can be targeted in this regard in an attempt to affect the share of unpaid done by each but there is increased interest in encouraging fathers to take (short periods of) time off work to care for their very young children (as per the fathers' leave mentioned above). On the other hand, there is a general move toward activating people to be employed so as to raise the level of gainful activity (and associated sense of personal responsibility). This could be said to have a 'work–family reconciliation' character in that both female and male parents are increasingly encouraged to be economically active. It will be obvious that there is a certain tension – if not contradiction – between the two types of 'reconciliation.'

International policy actors (especially the European Union and OECD) have played a major role in driving forward and legitimizing these (and other) philosophies. While their main concern lies with broader economic and/or political goals, both the European Union and the OECD have been encouraging countries to develop a family policy that removes the barriers to labor market participation on the part of different family member (mothers especially) and enables child development. Of the two, the EU has gone furthest – setting ambitious targets (on both child care and female employment) and introducing laws compelling employment leaves for the purpose of child care.

All of this leads to one major set of conclusions. Family policy is a complex field and a domain of policy that is contested and fought over. It is also a sphere of social policy that reaches deep into society; in other words, it has many causes and consequences and normally involves economic, political, and social concerns.

Family Size Preferences

Elizabeth Thomson, Stockholm University, Stockholm, Sweden; and University of Wisconsin–Madison, Madison, WI, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Family size preferences may be represented by family size desires, intentions, expectations, and ideals. Desired family size is the number of children wanted in one's lifetime and is viewed as a measure of the demand for children which, in combination with the supply of children and contraception determines the number of children born. Family size desires are conceptually and empirically distinct from family size intentions, expectations, and ideals. Desires, intentions, and expectations are often uncertain and change over the life course in response to new experiences and conditions. Ideals are shaped by the larger society and therefore change more slowly. Because childbearing is a two-person event, desires and intentions of sexual partners must be considered. As predictors of aggregate or individual fertility, family size desires must be adjusted to take into account partners' desires and changes over the life course, as well as fecundity, fertility control, and other constraints on individual behavior or outcomes.

Conceptualization and Measurement

Desired, Intended, Expected, and Ideal Family Size

Desired family size is conceptualized as the demand for children, that is, "the number of children parents would have if there were no subjective or economic problems involved in regulating fertility" (McClelland, 1983: p. 288). Desired family size is the basis for estimating the level of wanted versus unwanted fertility (Bongaarts, 1990, 2001). Family size intentions, on the other hand, reflect a decision to implement specific behaviors required to achieve a particular number of births (Miller, 2011). As such behaviors occur in sequence over a relatively long period of time, the concept of intention is better suited to a particular birth than to cumulative family size. Family size expectations incorporate both family size desires and perceptions of the likelihood that preferences can be translated into outcomes. Intentions and expectations are conceptually very close, but expectations incorporate a greater degree of uncertainty, especially with respect to changes in desires and circumstances and degree of fertility control. In settings with high levels of fertility control and for persons with high levels of efficacy, intentions and expectations may be empirically indistinguishable. The gap between desires and intentions or expectations arises from partner's desires, perceived fecundity and fertility control, or other known constraints on fertility behavior or outcomes (Bongaarts, 1990; Miller, 2011).

Ideal family size is of a quite different character. Personal ideas would be equivalent to desires, if there were no constraints on having children and perfect fertility control. In low-fertility contexts where costs of children and fertility control are high, personal ideal family size is larger than expected family size (Testa, 2006). Family size ideals are most often, however, specified for the population at large and in that respect constitute a social norm (Trent, 1980; Mason, 1983; Hagewen and Morgan, 2005; Testa and Grilli, 2006). Livi Bacci (2001) suggests that when fertility is very low, desired family size may not be a good indicator of fertility demand because it is strongly influenced by stereotypes of the normative two-child family. The same argument could be made for social contexts in which fertility is very high (Nauck, 2007).

Family size desires, intentions, expectations, and ideals are generally specified in terms of a single number of children. Terhune and Kaufman (1973) argued that family size desires should be conceptualized as a utility function with varying values across parities. For some, the function might have a clear peak, perhaps even only one family size with positive value. For others, the function might be relatively flat, with only extreme family sizes producing negative value. A similar function could be specified for family size expectations where each possible family size is assigned a probability, ranging from zero to one. The fact that one cannot intend two alternative outcomes at the same time makes it impossible to conceive family size intentions in a parallel fashion, again suggesting that intentions are better suited to sequential rather than cumulative childbearing. Ideal family size by definition requires a single choice among family sizes, but the aggregate distribution in a population of ideal family size can be viewed as a functional representation of the strength as well as content of a childbearing norm.

Measurement

Two types of questions are most commonly used to measure family size desires. The first asks respondents how many children they would want to have in their lifetime, if they could choose the exact number. For childless respondents, this question measures desires prospectively; for parents, the question includes a retrospective assessment of previous births with a prospective assessment of potential future births. Retrospective assessments of birth wantedness are subject to social desirability bias or rationalization and therefore produce upwardly biased estimates of desired family size (Bongaarts, 1990; Williams and Abma, 2000). Another version of this question attempts to give respondents permission to report previous births as unwanted by asking something like: "If you could start life over again, how many children would you want to have?" McClelland (1983) suggests that such questions produce less reliable and valid measures of fertility demand than prospective questions.

The second type of question asks respondents how many more children they would like to have; for childless respondents, the answer would presumably be the same as for the first type of

question, but for parents, retrospective assessments of previous births are excluded. To obtain an estimate of desired family size, some analysts simply add the respondent's current number of children to the additional number desired. This strategy assumes that all previous births were wanted, producing an even stronger upward bias than does the first type of measure.

Measures of family size desires that allow for a range of acceptable, possibly equally preferred family sizes require more questions (Terhune and Kaufman, 1973; Coombs, 1974; Ballweg and Klemmack, 1984; Hin et al., 2011). Scales based on unfolding theory (I-scales) distinguish preferences for number (IN) and sex (IS) of children (Coombs et al., 1975). Despite their superiority to single-choice measures in terms of reliability and predictive validity (see below), such measures have seldom been used in large-scale surveys.

Family size intentions, expectations, and ideals are also almost uniformly measured with questions that ask for a single choice. As intentions or expectations are oriented to the future, family size intentions or expectations are measured as the sum of the number of children already born and the number of any additional intended or expected children.

When family size desires, intentions or expectations are specified in terms of a specific birth, measurement is generally more precise. Desires may be measured along dimensions of intensity, centrality, and certainty (Schaeffer and Thomson, 1992; Thomson and Brandreth, 1995) and may incorporate both positive and negative components (Miller and Pasta, 1995). Intentions may be specified in terms of certainty (Thomson, 1997) and expectations in terms of likelihood or probability (Thomson and Brandreth, 1995).

Nonnumerical Responses and Uncertainty

In high-fertility societies, small but significant proportions of respondents do not provide a numerical response to questions about desired family size, reporting instead that the number of children they have is 'up to God' or that they will accept whatever number of children they have. These responses represent a completely flat family size utility function both theoretically (Terhune and Kaufman, 1973) and empirically (Jensen, 1985). Because such respondents are willing to express numerical family size ideals or preferences for one family size over another, and do report unwanted or mistimed births (McClelland, 1983; Riley et al., 1993), the 'up to God' response might reflect moral objections to, or lack of possibilities for fertility control. In a context of high child mortality, 'up to God' may also refer to uncertainties about the number of children who will survive (Sandberg, 2005).

Even where individuals have high control over childbearing, they may be uncertain about how many children they want, whether they want any children at all, and whether they want a second, third, or higher order birth (Schaeffer and Thomson, 1992). They might perceive a close balance between the positive and negative outcomes of childbearing or simultaneously experience strong positive or negative motivations for children (Miller, 2011), and therefore be uncertain how they really feel or what they really want.

When respondents are asked to state birth intentions – i.e., a plan to carry out behaviors that will result in a birth or not – they often express uncertainty. Uncertainty is inherent in the theoretical construct of fertility expectations as unknown changes in external conditions and events must be taken into account. Uncertainty in intentions or expectations may arise from uncertain or weak desires or from uncertainty about future conditions for rearing children or success with fertility control (Ní Bhrolcháin and Beaujouan, 2012). As Ní Bhrolcháin and Beaujouan (2011: p. 120) point out, "… uncertainty is a reasonable response to the many contingencies and unknowns that people encounter through the life cycle …."

Uncertainty about ideal family size should theoretically arise only if one is ignorant of the conditions and behaviors in the society at large. Those who do not know or refuse to provide an ideal family size are most likely to be expressing acceptance of a range of family sizes. In many countries, a small but significant proportion of respondents assert that there is no ideal family size (Hagewen and Morgan, 2005; Testa, 2006).

Changes in Family Size Desires, Intentions, Expectations, and Ideals

A major criticism of the concept of desired or intended or expected family size is that births usually come one at a time. Each birth provides new information that may influence future childbearing desires, intentions, and expectations (Namboodiri, 1983). Other experiences also intervene to change the perceived benefits and costs and the desire, intention, or expectation of having a particular number of children.

Miller (2011) argues that desires for children are more stable than intentions and expectations because they are linked to personality traits. Ní Bhrolcháin and Beaujouan (2012) argue to the contrary that the pervasive ambiguity in fertility desires is evidence that they are socially constructed over the life course. They go so far as to suggest that desires for children may be constructed in the process of answering survey questions (see also Schaeffer and Thomson, 1992). In both high- and low-fertility contexts, desires for children shift over relatively short periods of time (Bankole and Westoff, 1998; Miller and Pasta, 1995; Heiland et al., 2008).

The evidence is clear that family size intentions or expectations change over the life course (e.g., Freedman et al., 1965; Westoff and Ryder, 1977; Quesnel-Vallée and Morgan, 2003; Hayford, 2009; Liefbroer, 2009; Morgan and Rackin, 2010; Iacovou and Tavares, 2011). Changes are associated with experiences of the first birth, the influence of partners or educational and career trajectories. Changes in intentions or expectations generally occur within the range of normative family size (Freedman et al., 1965; Bankole and Westoff, 1998; Morgan and Rackin, 2010).

Changes in ideal family size may also occur at the individual level, but as indicators of change in social norms are of greater interest at the societal level. In low-fertility countries, ideal family size has been exceptionally stable, with the vast majority specifying two children. In recent years, significant downward shifts have been identified in a few European contexts (Sobotka, 2009). Goldstein et al. (2003) argued that persistent fertility under two children per women could shift ideal family size to well under two.

Her, His, and Their Family Size Desires, Intentions, and Expectations

Most data on family size desires, intentions, or expectations come from interviews with women, while ideal family size is more often asked of women and men in general-purpose social surveys. The assumptions underlying women-only fertility surveys are that (1) women and men share the same conditions of life and will therefore want, intend, and expect the same number of children; (2) because women bear children and are primary child rearers, their desires and intentions are those that determine fertility; and/or (3) women's desires, intentions, and expectations will incorporate those of their partners, reflecting resolution of any initial disagreements. In the aggregate, women's and men's respective family size desires and intentions are more similar than different (Mason and Taj, 1987; Bankole and Singh, 1998; Testa, 2006). Data collected from couples, on the other hand, consistently show that substantial proportions disagree about desires, intentions, or expectations for further childbearing or completed family size (e.g., Coombs and Fernandez, 1978; Thomson et al., 1990; Becker, 1996; Thomson, 1997; Bankole and Singh, 1998; Mason and Smith, 2000). Furthermore, when partners express diverging desires for children, they influence one another's intentions to have a child (Morgan, 1985; Miller and Pasta, 1996; Thomson, 1997). Thus, couple disagreement is a primary source of gaps between desires and intentions or expectations.

Family Size Desires, Intentions, and Births

The relationship between family size desires and births depends on relationships between desires and intentions, intentions and behavior, and behavior and outcomes. In addition to couple disagreement, a key source of gaps between desires and intentions or expectations is the perception of control over fertility. Those who believe themselves to be infecund may desire more children than they intend or expect; those who do not perceive themselves to be able to control fertility may intend or expect more children than they desire. Perceived social norms are also potential constraints on the translation of desires into intentions and subsequent behavior (Billari et al., 2009).

Measures of family size desires, particularly the desire for additional children, are strongly associated with eventual births at the aggregate levels (Bongaarts, 1990; Pritchett, 1994). Lee (1980) has demonstrated that a 'moving target' model of desired and achieved fertility produces even stronger correspondence between family size desires and period fertility. Bongaarts (1990) developed a model for adjusting average desired family size for upward and downward biases; the adjusted value is even more strongly associated with the total fertility rate than the initial value.

At the individual level, the relationship between childbearing desires or intentions and subsequent births is also quite strong (Westoff and Ryder, 1977; Schoen et al., 1999). The strength of the relationships depends on the length of time between observation of desires or intentions and births, the strength of desires or certainty of intentions, the capacity for fertility control, the strength of opposing social norms and other conditions that might inhibit the translation of desires into behaviors (Davidson and Jaccard, 1979; Philipov, 2009; Hayford and Agadjanian, 2012). A key element is an agreement between the sexual partners. In virtually every study that includes the desires or intentions of both partners, their joint childbearing is influenced by the desires or intentions of each (e.g., Becker, 1996; Miller and Pasta, 1996; Thomson, 1997; Thomson and Hoem, 1998; Bankole and Singh, 1998; Becker, 1999; Mason and Smith, 2000).

Estimated relationships between fertility desires, intentions, expectations, and births also depend on measurement quality. The IN-scale discussed above provides more accurate measures of preferences and therefore has larger estimated effects on fertility behavior than does the single most preferred number of children (Coombs, 1979). Measures of the desire for children that incorporate dimensions of attitude strength have stronger effects on childbearing intentions and behavior than do yes-no-do not know responses to direct questions about desire for children (Thomson and Brandreth, 1995). Similarly, intentions or expectations measured with some degree of certainty or uncertainty are better predictors of births than a simple dichotomy (Thomson, 1997).

Family: The Anthropology of the Concept and Its History

Jean La Fontaine, University of London, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The family is both a significant institution in Western culture and a technical term used in analysis. This article deals with both aspects. A consideration of its significance in Western social life first establishes its importance. Then, a history of the anthropology of the family shows the difficulties entailed in trying to find a neutral approach to facilitate a more cross-cultural and theoretical understanding.

Introduction

The family is both a significant institution in Western culture and a technical term in cross-cultural analysis. From the start, its great importance in Western culture has given it a central place in anthropology. However, a series of problems arise when 'the family' is used as a basis of comparison with other societies. Simplifying the concept by identifying one or other of its component elements as fundamental has not solved the problems in cross-cultural analysis, but has preserved the illusion that 'the family' is a useful theoretical tool. A history of the anthropology of the family shows the difficulties entailed in trying to find a neutral approach to it and a general theoretical understanding of the ideas and practices it entails.

The Family in Western Society

The significance of the family in Western societies is obvious in daily life. Children in primary school are asked to describe their families as a writing exercise and politicians vie with one another to be 'the party of the family.' Christianity, the majority religion of Western society, celebrates the Holy Family and its priests proclaim the duty of Christians to emulate it in their domestic life. The private life of individuals is identified with 'the family'; it is 'the building block of society,' given equal weight with the public institutions of the state, since the division into public and private spheres of life is one of the fundamental social distinctions in Western culture.

The social unit to which the term family is usually applied consists of parents and children; the importance of this unit is signaled by the fact that the terms used by its members for one another are not applied to any other relatives, which is not the case in other societies; the relationships these terms designate are seen as unique. Sometimes labeled the 'nuclear family' this form may be described as 'natural,' the consequence of the long period of maturation required by the human child, rather than a socially defined unit and those adults who have neither spouses nor children might once have been regarded as not fully adult.

The idea that the family is a natural unit and perceived as such has been a difficulty in cross-cultural comparison. This idea as a misperception can be readily shown by listing the multiple uses of the term in common speech. Despite its importance, the word 'family' has no single, clearly defined meaning. In twenty-first century England, in ordinary speech, 'family' may evoke any one of a cluster of meanings, depending on context. Harris (1983: p. 31) lists six different meanings ranging from parents and children to status and historical continuity. It is difficult to claim that any of these meanings is the 'true' meaning and others are merely derivative usages, although some people might argue that the unit of parents and children is the primary sense of the term. However, there is evidence to show that this meaning is relatively recent in English history. Davidoff and Hall (1987) trace its importance to the rise of the industrially based middle-class in the nineteenth century. Before that time, 'family' referred to the residents of a single household, including the kin and servants of its recognized head. The association of residence with 'family' persisted and the residential dimension was transferred to the new 'nuclear family' despite the fact that household and family were not always identical in composition. As historical research has subsequently shown, households have long varied in composition from small nuclear units to large communities containing servants and other employees, relatives, and foster-children.

The family is not an isolate but part of a system of relations traced more widely, but based on the same concepts. This may be referred to as the extended family but anthropologists use the term kinship. Networks of kin ramify and are spread widely, genealogically and geographically (*see* Kinship in Anthropology). In most societies in the world, kinship is more significant than 'family' and kinship relations may underlie social frameworks of much wider social significance than the household. The comparison has also shown that the distinction made between relationships within and outside the family has obscured the significance of the kinship system in Europe, and it has drawn very little attention even from anthropologists.

The Anthropology of the Family

The issues with which the anthropology of the family has been associated reflect ideas implicit in the Western concept. The polyvalence of the meanings associated with 'the family' results in a variety of conceptual problems for the would-be neutral anthropologist.

At the outset the focus was developmental; it gave priority to the setting up of 'a family' that is marriage, which was then considered to be the 'foundation' of the family. In the nineteenth century, the scholars who developed anthropology regarded monogamous lifelong marriage as a characteristic of 'civilization,' the culmination of human evolution. The Western family was seen as a late development not to be found among peoples who represented earlier stages of the evolutionary process. These latter were characterized by plural marriage and their classification of related individuals was thought to show failure to understand the nature and significance of biological links. Nineteenth century evolutionism has long been recognized as lacking a sound empirical basis for its conjectures, but the idea that the present form of 'the family' is a product of social changes over time has not been entirely abandoned. It survived in a modified form in the view that the present form of 'the family' is a product of modernization, of capitalism, or of industrial society and, by contrast, in the myth that Europe's peasant forebears all lived in extended family groups.

By the middle of the twentieth century, some anthropologists argued an opposed view, claiming that the family could be said to be universal, even though contained within many different forms of residential unit. The basis for this conclusion was the assumption that 'the family,' so far from being associated with marriage in a particular cultural form, was based on a universal natural function, reproduction. It was this 'biological fact' that formed the basis of the family, a view characteristic of the societies from which anthropologists came. 'The family,' a couple with their children, might be incorporated in various different domestic arrangements, but was itself a biological 'given.' Whether any individual society recognized this or not was said to depend on their culture, a view not totally unlike to that of the evolutionists with whom they disagreed. Murdock (1949) proclaimed the nuclear family to be universal, a coresidential unit with 'sexual, economic, reproductive, and educational' functions. His conclusions depended on ignoring a good deal of information on the wide variety of social units associated with these functions. The procedure showed all too clearly the looseness of the term 'family.' Malinowski, an earlier proponent of this functional view, had nevertheless cautioned that "…the essential features of the individual family depend upon the general structure of a given society…" (1913: p. 6).

A consideration of social structure built up on the roles associated with membership of a family introduced new factors. Starting from marriage as the founding of a new family, the tie between spouses can also be seen as linking distinct 'families,' since husband and wife do not lose their roles in the family in which they were children. Individuals are thus members of at least two 'families': one in which they are children and (usually) siblings and one in which they are spouses and (usually) parents. Sociologists have labeled these the family of origin and the family of procreation, which emphasizes the different methods by which the focal individuals are recruited, i.e., birth and marriage.

Anthropological research in other societies revealed different associations of kinship and household structure which made it necessary to develop a terminology for cross-cultural comparison. The establishment of different types of 'families' such as the 'stem family' of Japan (consisting of one married pair from each of two, or even three, successive generations and their unmarried children it is also to be found in Eastern Europe and extending from the rural areas of Eastern and Southern Europe) or the 'extended family,' meaning large households containing three or more generations, which can still be found in India and Africa. The term 'matrifocal family' was coined by R.T. Smith to describe the Caribbean household of mother daughter(s) and grandchildren with men only visiting or temporarily resident (Smith, 1973). This form is now also found among poor black families in both the USA and Great Britain. A large number of related households living associated as one community may also be referred to as an extended family, identifying their common locality as similar to residence in a single household. All these uses of the term became current in academic works (Janssens, 1993 (it is also to be found in Eastern Europe and extending from the rural areas of Eastern and Southern Europe)).

A solution to the theoretical problems raised by the data on domestic organization was to distinguish between 'the family' as a reproductive unit and the household as a residential group. One of the first to do this was Fortes (1958) who used the term domestic group, referring to the 'family' as the reproductive nucleus within it. His distinction emphasized a number of contrasts between the concepts: 'the family' consists of parents and children, whereas the domestic group might include more than two generations and other kin; the family is recruited through marriage and parenthood, whereas many different kinds of tie may draw individuals into living together. The family is concerned with social and physical reproduction; the domestic group 'is essentially a householding and housekeeping unit' (Fortes, 1958: p. 8). According to Fortes, the differences in the size and structure of domestic groups that can be observed in a particular society do not reflect breaches of any 'rule of residence' as had previously been thought, but reflect the developmental cycle of growth and maturation in the reproductive nucleus, or, in some cases, nuclei (Fortes 1949). They may also display the effect on household structure of the political and economic institutions of the society in question. These processes and the cultural reactions that they entail are the driving forces behind household changes.

The distinction between 'family' and 'household' also drew attention to economic production as a household activity. Property rights and labor needs were shown to influence the form of the domestic group as much as the developmental cycle of the reproductive core. Households were shaped by the demands for different kinds of labor associated with their subsistence activities that might vary according to the season, and the association of related people within different households concerned economic viability as well as kinship obligations (Stenning, 1958). Goody went further and showed that interpersonal relations in the 'reproductive core' were also affected by these factors (Goody, 1956, 1976). Marxist anthropology subsequently attempted to construct different modes of domestic production and reveal the power structures entailed in them, but these largely ignored reproductive processes and were not widely adopted.

In recent years, attention to relationships in households and localities has emphasized the association based on criteria other than kinship. This underlines the difference between family and household by focusing on the generation of relationships among individuals and the meanings attached to the process rather than a formal structure of roles (Carsten, 1995, 1997).

The view that the family was a 'natural' phenomenon had been reflected in a similar view of the universal existence of rules restricting sexual relations within the 'nuclear family' to the conjugal pair. These rules, insofar as they affected the family, were known as the incest taboo; the use of the term 'taboo' denoted their strict nature and implied the pollution that in many societies was believed to follow any breach. It was argued by Westermarck (1891) that these relationships were such that sexual attraction 'naturally' did not arise because the nature of daily interactions destroyed such feelings. Others, like Malinowski, argued *per contra* that the prohibition of sex between siblings and between parents and children was essential to the maintenance of authority and the prevention of conflict within a basic social unit and so was not natural but fundamentally social (Malinowski, 1926, 1940).

The later development of sociobiology returned to the support of the 'natural' basis of the incest taboo, claiming that the incest taboo could also be observed to exist among the higher primates and was therefore genetic, rather than a feature of human family relations. This, like other forms of biological determinism, was vigorously contested by social anthropologists (Schneider, 1965; Sahlins, 1976). In particular, it was pointed out that paternity is not identified by the higher primates and among human beings it is always socially determined. The accumulation of data on other societies made clear that sexual prohibitions of an identical nature extend outside the family in all societies and include unrelated people such as affines or step-relations. That this was also the case in Western society had been largely ignored (La Fontaine, 1990). Incest taboos, considered as total systems of prohibitions, varied widely cross-culturally. The prohibition on incest could not therefore be considered biologically determined or 'natural' (Goody, 1956).

Few social or cultural anthropologists now accept that the incest taboo is genetic or universally the same, but the conviction that among close kin it is only rarely broken and that incest is 'unnatural' lingered on. By the end of the twentieth century, however evidence that breaches of the incest taboo were infrequent, but not rare in Western societies and became public knowledge with the reporting of cases of the sexual abuse of children by their fathers or (less often) brothers. This offered proof that the 'taboo' was neither genetic nor unbroken (La Fontaine, 1990). The reality of incest was not easily accepted, whether by the public at large or by social scientists, showing that the assumptions underlying it and also the concept of the family it upheld were deeply rooted in Western culture.

A significant finding of anthropological research in many parts of the world was that the ways in which relatives might be classified was both varied and amenable to analysis as systems, which might then be compared. Kinship categories cut across both reproductive and domestic units so that, for example, it was (and is) not uncommon for women to be addressed as 'mother' who have no biological connection with the speaker. This is not merely a courtesy title as might be the case in some parts of England for example. While the means of identifying the 'birth mother' exists in most societies, what Westerners perceive as a biological tie between two individuals is not as significant in other societies as their relative positions within the kinship system as a whole. In effect, the classification of kinship in other societies and the terminology in which it was expressed did not single out the nuclear family, nor distinguish 'biological' from other kinship relations.

In addition, it became clear that kinship systems incorporated a local view of what constituted distance and closeness of relationships that might be linked to a perception of biology different from that underlying the western family. For example, distinctions are made in many systems between relatives linked through men and those related through women. Father's brother and mother's brother are defined in many societies as different kind of kinsmen and the justification for this may be the conviction that the tie between a child and each of its parents is not equally 'natural.' The extreme view, found in some Australian and Melanesian societies, denies the male contribution to conception altogether so that a father is not believed to have any biological link to his children, their relationship is established by his marriage to their mother. The opposite view, the denial of maternal contribution to the substance of her child occurs in a few patrilineal societies whose members consider women merely incubate the child placed in their womb by its begetter. If the family were to be considered universal, the recognition of a 'natural' unit, then the existence of societies that explicitly deny this would have to be reconciled with the theory.

At intervals during the last 50 years, anthropologists have pointed out the deficiencies of the concept of the family as an analytical tool (Fortes, 1958; Yanagisako, 1979; Schneider, 1984; La Fontaine, 1985). Robertson's solution to the problem is an original one. He starts with an account of the importance of the idea of the family in Western culture; later, he draws attention to social scientists' 'fixation on the family' (1991: p. 154). As he points out these two phenomena are undoubtedly connected. He argues that reproductive functions were wrongly attributed to the family, which is merely part of one version of the social construction maintaining the continuity of any society by ensuring the regular replacement of its aging members by the next generation. In order to compare the various cultural forms that enable reproduction, the concept of the family is discarded. Reproduction, social and physical, is universal but the cultural form that ensures it is society as constituted in particular forms. Robertson's approach implies that all that can be compared as reproductive systems are social wholes, which had been briefly tried and rejected by anthropologists as unwieldy and unproductive (Benedict, 1934). A logical consequence of this position is that the function of physical reproduction should be ignored both as the origin of the family and as an issue in anthropology. Robertson argues that the idea of the family, like other

cultural values with which it is associated, imposes a permanence and order on a reality that is always in flux.

Another approach came to the same conclusion as Robertson but from a different angle. Under the rather more materialist influence of feminism, anthropologists in the 1980s showed how the 'natural' processes of childbirth seemed to be very widely used to symbolize women and legitimize their subordination to men. Within the domestic sphere, also associated with women, the division of labor was seen as reflecting the natural capabilities of men and women; the products of their labor were shared with their children. However, the distribution of goods and the allocation of labor within the household actually reflected its internal power structure rather than a pooling of family resources or a 'natural' division of family labor. The realities of power were presented as unquestionable by being associated with the natures of men and women. Concepts of nature were thus shown to be more than mental constructs; they were also intimately bound up with the social distribution of power and authority, which they helped to legitimize and reproduce. The 'family' and its reproductive function was revealed as a symbolic representation legitimizing household organization (Harris, 1981). Nature stands as a symbol for what is a fundamentally social unit.

These views were stimulated by the work of the French anthropologist Lévi-Strauss' work on symbolism and meaning. His revolutionary approach to kinship used it to dispose of some of the questions that have been raised. He argued (Levi-Strauss, 1958, tr.1963) that exchange of goods and of women, not biological reproduction, was the basis of social life. Hence, marriage rules are integral to the wider social structure, not merely the basis of the family or a means of recruitment to households. Systems where marriage with relatives was the ideal showed how the patterns of distribution of women in marriage constituted social structures. His 'atom of kinship' (Levi-Strauss, 1958, tr. 1963) contained the same elements as 'the nuclear family,' but rearranged so as to emphasize the relation between a man and his wife's brother created by marriage. He argued that the pairs of opposites that were the elements of the 'atom of kinship' reflected basic oppositions in systems of thought, the deep structure of culture.

While Lévi-Strauss' structuralist approach undoubtedly revealed the significance of cultural understandings of the world, he was less interested in distinguishing between the meanings drawn from the analysts' own Western culture and those of the societies they were studying or in comparing them. His work, immensely influential though it was, took the comparative study very little further. However Lévi-Strauss' emphasis on the symbolism of cultural concepts, including that of nature, was fruitfully applied to the study of kinship systems. Schneider analyzed American kinship in terms of the conjunction and contrast between concepts of nature and concepts of law (Schneider, 1968, 1972). 'The family' is the source of basic elements that categorize kinship relations beyond it, extending to relations with affines and more distant kin. Marriage, conceived of as taking place between unrelated persons established the legal–cultural relationship between spouses whereas kinship between parents and children was deemed natural – though only in the sense that the natural world was perceived through the medium of culture. There is thus in Schneider's approach, a distinction to be made between the material nature of the world and cultural constructions of that world (the cultural construct of nature). Ethnoscience, the cultural understanding of the natural world, is to be distinguished from formal science where evidence and proof support conclusions. Schneider makes a further distinction when he states that cultural concepts of nature can be used as symbols to enhance the significance of important elements of culture and this is what he perceives to be the role of 'nature' underlying the concept of the family. Human reproduction conceptualized culturally as parenthood represents nature while marriage, being purely cultural, denotes 'law.' In fact, Schneider remarks "kinship is biology" (Schneider, 1968: p. 116).

Barnes in his critique of Schneider (Barnes, 1973) starts from a Lévi-Straussian opposition between nature and culture, the latter being virtually the same as Schneider's 'law.' He points out that parenthood is not entirely 'natural' as Schneider would have it; 'the relations of nature to fatherhood and motherhood are different' (Barnes, 1973: p. 72). Whereas physical motherhood (the status of genetrix) is demonstrated at birth, no matter who rears the child, no such event defines physical paternity (the genitor). Conception cannot be perceived and was not understood in Europe until relatively late in history, but it was believed to involve both partners long before science had demonstrated the process. If we then consider the cultural elements in the family it becomes clear that fatherhood must be associated with marriage as cultural, not natural. It is marriage that defines the paternity of children whatever the physical reality of their conception. Considered comparatively, paternity is a 'freer symbol' (Barnes, 1973: p. 71), owing less to biology than maternity and thus can show greater cultural variation, as, indeed it does. Thus the mother–child tie is the only kinship relationship that can be said to be in any sense, 'natural' (see Fortes, 1958 for an earlier statement of this point of view) and concepts of 'the family' and of 'kinship' partake of both elements.

Marilyn Strathern subsequently argued that in providing new methods of 'assisted parenthood' science will undermine the idea of the family as being fundamentally 'natural' (Strathern, 1992) and destroy the concept of relatedness seen as extending outward from the nuclear family. In particular, the possibility of 'surrogate motherhood' whereby a woman gives birth to a child which is the genetic offspring of another woman to whom it will be given will undermine the notion of motherhood as based in biology (Edwards and Strathern, 2000). An earlier discussion of the same topic (Wolfram, 1987) came to rather different conclusions. Looking at historical and literary evidence as well as more recent legal debates, she concluded, "change can often be accommodated in existing categories" (Wolfram, 1987: p. 214), and her discussion takes into account the role of law as equally involved. One might also add that children had been brought up by people who were not their genetic parents for centuries before the law on adoption in 1928 made it legal and often enough it was not known that the women they called mother were not biological relations.

The idea of 'the family' has always been a poor fit with social reality. Mothers have adopted the illegitimate children of their daughters as their own or kinswomen have taken in children whose mothers died or were unable to manage large numbers of children. Adultery and extramarital conception resulted in legitimate paternity not being matched by the genetic constitution of children. Early deaths made step-relations common. Yet the concept of 'the family' survived these diversions by reality. Perceptions may have changed among patients of the clinics offering reproductive technologies where research has largely been done, but it seems just as likely that in the wider society, the understandings of human reproduction which they accept as science-based views of nature, but which anthropologists argue are moderated by culture, still remain relatively unchanged.

At the same time, a rediscovery of the significance of relationships based on locality and residence emphasized other means of creating relationships than those traditionally considered. The collection of essays edited by Carsten and Hugh-Jones (1995) was published at a time when interest in the family and kinship had declined and helped revive interest in domestic life. Demonstration of the many different ways in which membership of a domestic group can be established and the household related to its neighbors seemed to make the study of kinship alone too narrow and partial.

As a result of these separate approaches to the study of the family a focus on the folk concepts of relatedness was suggested (Carsten, 1995: p. 225; Carsten, 2000). Close ties may be based on shared residence, shared economic ties, nurturing or sharing food, gifts, and indebtedness or other forms of interaction. Interaction between meaning and action is thus reestablished as significant. This is not to say that kinship disappears however. Lambert argues that in North India, "consanguineal kinship constitutes the ideal model of relatedness and optative forms of relation invoke this model rather than being entirely identified with it" (Lambert, 2000: p. 85). Folk theories of relatedness constitute important sources of data for the anthropologists but they are not explanations that can contribute to anthropological theory, which must have general relevance if it is to be valid as a discipline.

While it may be generally accepted that the concept of the family is unhelpful, the term continues to be used. Thus, Segalen and Zonabend, having noted that under the influence of anthropology the 'overfluid' concept of the family has been replaced by analytical concepts such as household and kinship (1987: p. 112), then use 'family' unreflectively and do not discuss why or in what sense. Goody, the doyen of anthropological studies of domestic kinship, continues to write of the family and assert the European view that it is based on biological necessity (Goody, 1983, 2000: p. 1). This seems accurate, descriptively, of the European ethnography but it does not facilitate comparative study.

A final strand in late twentieth century anthropological thinking on 'the family' has been contributed by research in Europe and on issues of public concern (La Fontaine, 1990; Simpson, 1998). Simpson argues for the study of divorce, not as a social problem or a symptom of family or social breakdown, but as the reorganization of interpersonal relationships in new forms of kindred that are just as much a part of present day culture as 'the family.' Simpson's rejection of 'the family' as a theoretical model is explicit, but his continued use of the term, even qualified as 'the unclear family,' implies, as does the usage of Segalen and Zonabend, a tacit attachment to certain connotations of it that have yet to be made explicit. The concept of the family may have been discarded from the repertoire of many anthropologists but it is too soon to regard its relegation to the scrap heap as final.

Family Theory: Competing Perspectives in Social Demography

Abstract

Demographic research on families has relied on two key theoretical approaches: sex-role specialization in marriage and the economic significance of an independent nuclear family for shaping family-related behaviors. In this article, I address how these two approaches are linked to economic behavior and consider their potential ramifications for shifts in marriages and families.

This article examines two competing theoretical perspectives on recent changes in marriage and family behavior in industrial societies, their determinants, and consequences. Each focuses on the role of one of two fundamental pillars underlying most demographic research on the family: (1) the implications for family behavior of an independent nuclear family system and (2) the importance of sex-role specialization in marriage. The specialization perspective argues that the desirability of marriage is based on sex-role specialization with women focusing on domestic production (and reproduction) and men on market work. Hence it concludes that the rapid postwar rise in women's employment made them increasingly independent of marriage, leading to a retreat from marriage as indicated by sharply declining marriage and fertility rates, and rising marital instability as well as nonmarital cohabitation and unwed childbearing.

The specialization position has been subject to several major criticisms. Some of the most important are as follows: contrary to the theory's argument, empirical research shows that women in a better labor-market position are usually *more* rather than *less* likely to marry; the theory is one of *non*marriage while the phenomenon observed is primarily *delayed* marriage; and sex-role specialization in an independent nuclear family system tends to be a high-risk strategy and historically often required the use of the family's adolescent and young adult children to achieve economic stability, a role that now is taken over by wives. The independent nuclear family perspective has focused on how the changing economic position of young people has affected the ability of couples to be economically self-supporting. It has argued that the recent well-documented rise in economic inequality has increased the difficulty of assortative mating and of establishing an independent household. Studies indicate that men's employment stability and earnings have a strong positive effect on their marriage chances; moreover, the length of time it takes men to achieve career 'maturity' varies substantially among and within socioeconomic groups, creating significant differences in the age at marriage. A growing body of research demonstrates that these processes largely account for marriage trends in recent decades. Rising economic inequality in society coincides with the bifurcation of marriage and family patterns by education strata.

Two competing perspectives on the effect of postwar changes in the economic behavior of men and women on the family have characterized recent demographic research. Each primarily focuses on one of two fundamental theoretical pillars which underlay most demographic research on families in Western societies: (1) the economic implications for family behavior of an independent nuclear family system and (2) the importance of sex-role specialization in marriage. This article will undertake an examination of each of these perspectives in terms of these theoretical underpinnings, how they are affected by changing economic behavior, and the implications of this for changing patterns of marriage and family.

Overview

A number of major changes in marriage and family behavior have occurred in the West since the early 1970s. Age at marriage and marital instability has risen considerably while fertility has declined substantially (Blossfeld, 1995; Mason and Jensen, 1995; Oppenheimer, 1994). The magnitude of these changes has fostered considerable debate about their determinants and consequences and what these imply for the future of the family. However, in most cases, the debate is not so much about major theoretical differences on the nature of the family but differences in which aspects of two long and commonly accepted underpinnings should be emphasized the most. One is that marriage as an institution, as well as marriages as functioning social forms, is based on sex-role specialization. Although there are variations in how this specialization argument is conceptualized, the general idea is that the husband's role is largely economic while the wife's lies in the care of the home and in the reproduction and socialization of the children.

The second theoretical underpinning to most discussions is that an independent nuclear family system is a long-standing feature of populations of Western European origin. Such a family system is characterized by husband–wife families which are economically independent and live separately in their own household, although a single-aged parent might also have sometimes been included in the past. This is opposed to an extended family system which is usually characterized by joint family households consisting of several nuclear families. In general, historical demographic research has indicated that marriage and fertility behavior have often been quite different

in populations with independent nuclear as opposed to joint family systems. In the former case, marriage is contingent on the couple's ability to be self-supporting and able to set up a separate household; in the latter, the economic ability of the household as a whole to absorb new members has tended to be more important. Since young people's economic position is often precarious, the requirement of economic independence has historically led to somewhat later marriages and also to periodic fluctuations in marriage timing, depending on variations in economic circumstances. This has often resulted in substantial short- and long-term effects on fertility, especially in periods before the deliberate control of marital fertility became common.

This article focuses on two opposing positions regarding the effect of shifts in the economic behavior of men and women. One emphasizes sex-role specialization, arguing that the rising employment of women has been the major factor leading to the observed changes in marriage and family behavior because it has reduced specialization and hence permitted women to become economically independent of marriage, thereby reducing the gain to marriage. Assuming women's employment is unlikely to decrease, the result will be a major and irreversible transformation of the family in modern industrialized societies.

The opposing position is that the family has not been transformed as much as the women's independence argument maintains nor has women's rising employment had a negative effect on marriage formation, although it undoubtedly mitigates against high fertility. On the other hand, there is some evidence that deterioration in young *men's* economic position has had an important effect on marriage and family behavior because it has seriously affected the ability of young couples to set up an independent household. If so, then the assumed irreversibility of present trends is open to question, although it is extremely unlikely that a return to postwar patterns of the 1950–70s will occur.

These two alternatives do not exhaust the many possible reasons that have been proposed for changing family behavior, although they cover the major debates related to the effect of changes in economic behavior. Nevertheless, it is often the case that different explanations may be implicitly, if not explicitly, dependent on one or both of these positions. For example, it has been argued that modernization and the rise of individualism is the major force behind the recent demographic changes (*see* Second Demographic Transition). However, neither men nor women can be autonomous individualists if they are still economically dependent on traditional marital and kinship ties.

Independent Nuclear Family System

Given the assumption of sex-role specialization, demographic research on marriage and family behavior in independent nuclear family systems in preindustrial and early industrial populations has tended to focus primarily on the economic position of men, although there has long been a general recognition that women could help facilitate the formation of a marriage via earnings before marriage. In farming communities, marriage was often considerably delayed as the heirs had to wait for the father to die or retire before they inherited the property and with it the means of marrying. Even where leasing rather than owning land was the rule, as in England, there were often extensive delays until a man could save enough to lease a farm and set up a household. The effect of this pattern on marriage timing – and hence on fertility in historically non-contracepting populations – was often substantial with high proportions not marrying until their thirties and relatively substantial proportions never marrying (*see* Arensberg and Kimball, 1968; Goldstone, 1986).

With the growth of wage labor in the cities and on the farms as industrialization progressed, young men could much more easily become economically independent at a relatively young age. This promoted a reduction in the age at marriage, although offsetting factors were the need to save up to establish an independent household and prior obligations to contribute to the parental household, especially if one or both parents had died or were incapacitated in some way. In general, economic development also increased the sensitivity of young men's economic position to business cycles and structural changes in the economy. Recessions or depressions reduced marriage propensities, especially among the young, and recoveries led to sharp rises in rates. Moreover, the structural changes in the economy associated with economic development changed the skill levels and types of skills demanded of workers. This has placed an increasing premium on education and technical training in modern industrial societies which has, in turn, postponed the full-time entry of young people into adult-level employment and, with it, entry into marriage and the achievement of the degree of economic stability usually considered necessary for starting to raise a family.

Role of Relative Cohort Size

Postwar analyses of the influence of men's economic position on marriage formation and fertility was initially dominated by the work of Richard Easterlin who hypothesized that fluctuations in relative cohort size had a major impact on young men's labor market position, thereby affecting marriage timing and marital fertility (*see* Easterlin, 1987). Thus, Easterlin argued that the postwar baby boom, such as the one that the US experienced in the early postwar period, was largely caused by the favorable economic position of the small depression cohorts entering the labor market at that time. This encouraged them to marry earlier and have more children than previous cohorts. However, the relatively large cohorts they produced crowded the labor market, negatively affecting their lifetime earnings. This led to postponed marriage and childbearing, lower completed fertility, and greater marital instability. In addition, more wives would be working to compensate for their husband's poorer economic position. The result was smaller birth cohorts in the next generation – the baby bust cohorts – who presumably would be in a much more favorable relative labor-market position. According to the theory, this should lead once again to earlier marriage and childbearing, somewhat higher fertility, increasing marital stability, and the slowing of the growth in married women's employment. In short, the theory posited a self-perpetuating cycle.

The relative cohort size argument ran into empirical difficulties as research in the 1980s showed that postwar marriage and fertility fluctuations were largely *period* rather than *cohort* driven, i.e., fluctuations in demographic rates occurred simultaneously for numerous birth cohorts, regardless of cohort size. Moreover, the theory essentially accepted the premise that marriage is based on sex-role specialization. Women's labor-market behavior was considered to vary primarily in response to men's earnings position rather than in response to women's own employment opportunities, independent career goals, or family cycle variations in economic needs. However, women's employment continued to rise rapidly throughout the postwar period, regardless of variations in cohort size. As a result, the focus of research interest began to shift to the familial consequences of the transformation of women's economic roles.

Sex-Role Specialization

At the same time that relative cohort size argument (and hence male-oriented explanations of changes in marriage and family behavior) began to lose favor, the continuing rapid rise of married women's employment has seemed to provide a ready explanation for the ongoing changes in marriage and family behavior. Hence, the theoretical emphasis shifted from a concern with the ability to set up and maintain an economically independent household to the critical importance of sex-role specialization for family formation and cohesion.

The centrality of differentiated sex roles as an explanation of changes in marriage and family behavior reflects a long-standing and influential tradition in the social science literature on the importance of sex-role specialization for a stable marriage system. In the early postwar period, this idea was emphasized by Talcott Parsons (1949) who argued that sex-role segregation was a functional necessity for marital stability and even for the viability of society itself. More recently, this same theme has been elaborated somewhat differently in the economic theory of marriage by Gary Becker (*see* Family Theory: Economics of Marriage and Divorce). In an argument very similar to one Durkheim made over a century ago, Becker maintains that the major gain to marriage lies in the mutual dependence of spouses, each of whom specializes in certain functions – the woman in domestic production (and reproduction), the man in market work. Marriage then involves trading the fruits of these different skills. However, in response to economic growth and the rising wages it produces, women's market work also rises. The result is that women become less specialized and, as their earnings approach those of potential mates, more economically independent, leading, in turn, to a decline in the desirability of marrying or of staying married as well as the desirability of high fertility.

Many scholars do not necessarily agree with Becker's argument in its entirety. Nevertheless, an economic independence argument of one sort or another remains appealing among sociologists as well as economists and is currently one of the major contenders in trying to explain recent marriage and family trends in the United States (Cherlin, 1992; Oppenheimer, 1997). One reason is that the model seems to have tremendous face validity. Not only does the notion of specialized sex roles fit in with long-held views of how the traditional family historically functioned, but the rapid changes in marital behavior appeared to have followed very closely upon the rapid rise in married women's employment, especially that of young women. Nevertheless, the independence hypothesis has also run into a number of serious theoretical and empirical problems.

Mismatches

One problem the theory has encountered is that there are number of mismatches between the phenomena it claims to explain and the behavioral changes that are actually occurring. First, the independence hypothesis is essentially a theory of *non*marriage for it argues that if, by their own endeavors, women can achieve approximately the same income as a prospective spouse there is not much to gain by marrying and specializing in home production. However, so far, while there has been a considerable increase in *delayed* marriage, as yet there is little evidence of a substantial rise in *non*marriage (Oppenheimer, 1994; Blossfeld, 1995). In fact, Americans are unique for their proclivity to marry and remarry. According to Cherlin (2009), Americans are on a marriage-go-round. Although the age at first marriage in the US is at a historic high point, the vast majority eventually marry. Hence one reason for the apparent support for the hypothesis is due to a serious confounding of *delayed* marriage with *nonmarriage* in the statistics. Moreover, to date, there has also been little effort to articulate how the independence argument could lead to *delayed* instead of *non*marriage.

A major difficulty in assessing the outcome of recent marriage trends lies in the recency of the trends and the necessity of waiting 20 years or more before one can accurately determine whether there actually will be a significant rise in nonmarriage. Efforts to estimate the future proportions never marrying are often misleading because they typically use the current behavior of older people as a guide. However, during a period of rapid timing shifts, the *current* behavior of somewhat older people, who are the relatively sparse and atypical remains of much earlier marrying cohorts, is often a particularly poor guide to the future behavior of the much larger and less select group of younger people who have been delaying marriage in more recent years.

A second kind of mismatch lies in using the family behavior of the 1950s and 1960s in the US (and somewhat later in Europe) as typifying the traditional family patterns when sex-role specialization prevailed; compared to this, the large subsequent changes in marriage and family behavior certainly appear to represent a major retreat from marriage and the family. However, this was the baby boom era when fertility was unusually high compared to the previous 50 years; age at marriage was unusually low – far lower than at the turn of the century – and, in the US at least, even marital disruption was somewhat less likely than in previous years. In short, this benchmark was highly atypical historically and unrepresentative of the supposedly 'traditional' family (Coontz, 2004). Hence using the 1950s, termed the golden age of the family, as a benchmark, has led to a considerable exaggeration of the extensiveness of the subsequent break with historically

traditional patterns and of the historical origins of many recent trends.

There is still another type of mismatch characteristic of a theory which posits that the stability of the family is founded on women specializing in home production. The proposed model seems strangely out of tune with the needs and characteristics of modern societies. Much of the specialized home production of women in the past was devoted to bearing and rearing children who never survived to adulthood. For women to be equally occupied in contemporary low-mortality societies would result in large families. However, even moderate family sizes in a low-mortality society lead to rapid population growth. Moreover, couples do not just want to produce children per se, they want to produce children like themselves – that is, they are interested in social, not just biological reproduction. But the cost of social reproduction is high in a society where increasingly substantial and lengthy investments in human capital for each child are required. Hence, high fertility is usually not a realistic option for most people in modern industrial societies. With low fertility, however, the female specialist would not be doing anything highly productive for much of her life. In short, specialization in home production appears to be a rather anachronistic institutional role for women in industrial societies. Moreover, recent empirical work demonstrates that female labor force participation is *positively* associated with fertility in industrialized nations (Brewster and Rindfuss, 2000). Women appear to prefer to combine work and family.

Empirical Status of the *Independence* Hypothesis

The women's independence hypothesis has not been well supported by empirical evidence. At any given time, empirical analyses show that indicators of women's economic independence have not generally had a negative effect on marriage formation. For example, under an independence argument, better-educated women should be more economically independent of marriage; however, microlevel regression analyses show that, once school enrollment is taken into account, they have a *higher* rather than a *lower* propensity to marry. Although more educated women tend to delay marriage entry, they are ultimately most likely to ever marry. Indeed, women's education, earnings, and employment are all positively related to getting and staying married (Lichter et al., 1992).

The role of women's economic independence in divorce appears to be conditional on marital quality. Although women's employment and earnings are often positively associated with divorce, this relationship is actually more complex because it depends on the quality of the marriage. Among happily married couples, women's employment is not associated with divorce. Among unhappily married couples, women's employment is positively related to divorce, suggesting that economic independence allows women a pathway to exit an unsatisfying marriage (Schoen et al., 2002). This pattern has been established in other studies, too, including one showing that the effect of economic independence is a function of gender role ideology (Sayer and Bianchi, 2000). Marital quality was more closely linked to divorce than was women's economic independence, leading to the same substantive conclusion: women's economic independence allows women to leave bad marriages. Independence per se is not a driving factor in the likelihood of divorce. Still other work suggests that wives increase their market work in anticipation of divorce (Johnson and Skinner, 1986).

Coping with Risk and Change

Although rarely considered in explications of the theory, historical research on independent nuclear families indicates that extreme sex-role specialization in marriage is essentially a high-risk and inflexible family strategy unless accompanied by supplementary support mechanisms (Oppenheimer, 1994). Even with such supports, specialization often entailed considerable individual and social costs. An inherent problem is that the temporary or permanent loss of one specialist in a family can mean that functions vital to the well-being of the complementary specialist and children are not being performed. Husbands/fathers can die or become ill or disabled; they can lose their jobs and have difficulty finding another one; they could desert the family for a variety of reasons or become an alcoholic; and so on. The result is that the family is left without its major source of income. Except for employment-related shifts, there are similar problems involving the wife–mother specialist. In that case, there could be no one to take care of the children or the home. Specialization may be a feasible strategy in a large extended family household where no particular individual is indispensable because of the redundancy in personnel that can characterize such a system. However, for independent nuclear families and their individual members, specialization entails considerable risks.

Extreme sex-role specialization is also not a very flexible way of dealing with the varying needs of nuclear families over their developmental cycle. Since individuals' consumption needs and productive capabilities vary markedly by age, a basic feature of nuclear families is that the ratio of consumers to producers, and hence the family's level of living, can vary substantially over the family's developmental cycle. Hence, specialization involves a potentially serious inflexibility in dealing with changes in both a family's internal composition as well as the stresses posed by its environment.

The large literature on family history in Western societies indicates that a variety of strategies were developed to maintain economic stability over the family's developmental cycle and in the event of the temporary or permanent loss of specializing parents (Goldin, 1981; Haines, 1979; Rowntree, 1922; see Oppenheimer, 1994 for a review). In the nineteenth and early twentieth centuries these strategies usually involved utilizing the productive labor of children, daughters, as well as sons. The evidence also indicates that utilizing the labor of one's children could exact substantial costs. A sufficient number of children old enough to make an economic difference was generally not available until the middle or later stages of the family cycle. Families who temporarily or permanently lost the contribution of the father early in the family cycle were not greatly helped by such a strategy. If the mother was lost when the children were young, the family might break up with children being parceled out among relatives or even going to orphanages. In general, this economic reliance on one's offspring often led to a pattern of 'life cycle poverty' where periods of poverty and comparative plenty alternated over the life cycle of workers. Another

well-known disadvantage to the extensive employment of children to supplement their family's income was that it tended to discourage schooling and hence had a negative effect on children's adult socioeconomic status.

Even aside from the drawbacks of using children's work, the economic advantages of this strategy were eventually bound to decline during industrialization as the adult labor force became more skilled and hence the relative economic contribution unskilled children could make declined. This suggests that other equilibrating mechanisms were likely to develop. One mechanism may be governmental social support systems. At the family level, however, from a historical perspective, the rise in married women's employment might be viewed as a functional substitute for the work of their children, facilitating the more extensive schooling of the next generation and thereby fostering upward intergenerational social mobility. In addition, wives' employment is not limited to the later stages of the family's developmental cycle and wives, being adults, and usually having educational attainments roughly similar to their husbands, can command a much higher wage than unskilled children could. Moreover, recent research indicates that wives' earnings are currently playing an important role in offsetting the less favorable earning position of their husbands (Levy, 1998). It seems likely, then, that wives' employment could be a source of cohesion in marriages; in difficult times, a helpmate may be of much greater value than a complete economic dependant.

Even aside from wives' employment during episodic periods of an increased need for additional income, wives who work regularly may also increase the interdependence of spouses. Two-earner families where the couple pool their resources are families whose level of living is based on their *combined* income. Even when the income contribution of each spouse is equal, given economies of scale, neither partner could live as well on his/her own or save and invest as much. Hence, instead of the asymmetric dependence of the wife which is characteristic of complete specialization, there is a symmetric dependence where each spouse depends on the other to maintain living standards. What this may also indicate is that the combined income of the two-earner family has come to form the social standard rather than the husband's income alone. To the extent this is the case, it becomes increasingly difficult for single earners and married couples with a more traditional division of labor to achieve the same level of living as the two-earner family. Hence, the mutual dependence of the two-earner family may not only contribute to their own gain to marriage but may also reduce the relative gain to being single and to marriages characterized by a specialized division of labor.

In sum, it is unclear that specialization is the only, or even the optimum, method of creating cohesion in marital relationships in modern industrial societies. The specialization model itself seems highly problematic and women's rising employment may actually be promoting a more collaborative model of marriage.

Rising Economic Inequality

Given the empirical and theoretical limitations of the specialization model of marriage, research attention has been returning once again to the role of economic difficulties in setting up and maintaining an independent nuclear family. While the effect of relative cohort size earlier dominated research in this area, the more recent focus is on such issues as changing economic structure, chronically high unemployment rates (particularly among young adults), and rising earnings inequality (again especially among the young but also among the moderately-to-less educated as well). These analyses have also returned to the question of men's changing economic position which had been neglected for quite some time.

Virtually all recent research has shown that men who are more likely to be working full-time/year-round, had higher current earnings, and/or greater future career prospects were more likely to marry in any given short time interval (Clarkberg, 1999; Huinink, 1995; Oppenheimer, 1997; Oppenheimer et al., 1997). Some research in this area has also started to look at the role of economic factors in the formation of cohabiting unions and this indicates that here too, some level of economic stability is important, especially for the transition to marriage among cohabitors (Brown, 2000; Clarkberg, 1999).

Oppenheimer (1988) has theoretically and empirically elaborated on these issues in a variety of ways. First, she has conceptualized the transition to work as a career entry *process* rather than a *step*, which was more commonly the approach in previous life-course analyses. This change in approach emphasizes that embarking on a relatively stable occupational career takes time, during which a young man is in a relatively 'immature' career state. One aspect of career immaturity directly impeding the formation of an independent household is relatively low income; however, another is uncertainties regarding what kind of stable employment may eventually be achieved, when this may occur, what lifestyle the individual may ultimately expect or desire, and so forth. Such uncertainties can impede mate selection and affect the individual's own desirability as a prospective marriage partner. Hence, career immaturity is not only likely to foster delayed marriage for economic reasons but for social-psychological ones as well. Second, viewing the transition to work as a *process* expands the emphasis beyond the effect of career immaturity at any single point in time to the length of time it takes to achieve some career stability and the cumulative impact this will have on marriage timing. The delaying effect of only a modest effect of career instability in any given year, for example, may nevertheless have a large cumulative impact if the instability persists over many years. Moreover, this approach is well suited for examining how the length and difficulty of career development could vary substantially among different groups and over time as well, thereby facilitating analyses of socioeconomic differentials in marriage timing and trends in marriage behavior.

Using 12 years of an American longitudinal survey of young people, Oppenheimer et al. (1997) found that not only did a variety of indicators of career immaturity have a substantial effect in any given year on marriage formation, but that the cumulative impact was substantial when the career development process was followed over time. Moreover, there were large race–schooling differences in the length and difficulty of the career entry process which, in turn, produced major differences in marriage timing. Because the analysis was limited to the young adult life course of young men born between 1957 and 1964, how much of the rise in delayed marriage over

the past 25 years can be accounted for by career development problems has yet to be directly examined. However, there has been a substantial and well-documented rise in inequality in the US since the 1970s, and this has had a particularly severe effect on moderately-to-less educated younger workers, suggesting that career entry difficulties may be playing an important role in these trends. Indeed, there appear to be diverging destinies for young men and women as marriage increasingly becomes the province of the most highly educated (Cherlin, 2009; McLanahan, 2004). Marriage is now viewed by many as a luxury good or capstone experience and the bar for marriage has risen among all groups, effectively preventing many from achieving this milestone. To the extent that couples view financial security and good relationship quality as prerequisites for marriage (Gibson-Davis, 2009), these barriers can be insurmountable for a growing share of society as widening inequality hollows out the middle class. Many of the benefits of marriage, including co-residence and fertility, can be achieved outside of marriage through other pathways such as cohabitation. These developments give new urgency to a question that has vexed scholars in recent decades: to what extent is delayed marriage actually foregone marriage? Future research must address how and why the timing of marriage is changing.

Family Theory: Economics of Childbearing

John F Ermisch, University of Oxford, Oxford, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Economic theories of childbearing relate decisions about family size and the timing of births over people's lives to elements of the constraints on choice that people face, particularly prices and incomes. This article presents the basic concepts used in these theories, discusses their main lines of argument, and summarizes some of their empirical implications.

Economic theories of childbearing relate decisions about family size and the timing of births over people's lives to elements of the constraints on choice that people face, particularly prices and incomes. This article presents the basic concepts and approaches used in these theories, discusses their main lines of argument, and summarizes some of their empirical implications. It first examines 'static' theories of completed family size and then discusses dynamic theories of the timing of childbearing. While mainly concerned with theories of fertility in stable unions, it concludes with a discussion of nonmarital fertility.

'Child Quality' and Fertility

Economic theories of fertility have been around for over 200 years. The ones advanced by Thomas Malthus are the best known. In a few words, Malthus' view was that fertility was determined by the age at marriage and frequency of coition during marriage. He argued that an increase in people's income would encourage them to marry earlier and have sexual intercourse more often. Modern economic theories of fertility date from a paper by Becker (1960), which generalized and developed the Malthusian theory. Until Section Nonmarital Fertility, it is assumed that fertility decisions are made by a couple in a stable union.

Becker's point of departure is that children are usually a source of psychic satisfaction for parents. An important aspect of his seminal contribution was to point out that this satisfaction is likely to depend on the amount of resources that parents spend on children as well as the number of children that they have. The basic idea is that if parents voluntarily spend more on a child, it is because they obtain additional satisfaction from doing so. For instance, parents are likely to receive higher satisfaction if their children obtain a university degree than if they leave school as teenagers. For short, he calls children who have more resources devoted to them 'higher quality' children, hastening to add "that 'higher quality' does not mean morally better" (Becker, 1960: p. 211).

The characterization of 'child quality' in subsequent analyses has moved in the direction of identifying it with the lifetime well-being of the child ('quality of life'), which can be increased by investing more in the child's 'human capital' (i.e., his or her ability to earn income as an adult) or by the direct transfer of wealth to the child. That is, parents receive more satisfaction from having children who are better off throughout their lives, and they make monetary transfers and human capital investments to influence their child's lifetime standard of living.

Having incorporated the quality dimension of reproduction decisions, the well-developed model of consumer choice is applied to them. Parents are assumed to choose the best combination of the number of children, their quality, and the parents' own standard of living subject to parents' lifetime income and the prices that they face in markets. An increase in parents' income is expected to increase both the quantity and quality of children. Analogous to the tendency for people to increase the quality of most consumer durable goods proportionately much more than the quantity of such goods when their income increases, Becker argued that this is also likely to be the case for children. In economics, the 'income elasticity' of a good is defined as the percentage increase in the demand for that good in response to a 1% increase in income. Thus, using this terminology, Becker's contention is that the income elasticity of the number of children ('quantity') is small compared to the income elasticity of child quality. Put somewhat differently, an increase in parents' income may increase the amount spent on children substantially, but this would mainly take the form of higher quality rather than more children. The introduction of the child quality concept generalizes the Malthusian theory, which only allows responses to income along the quantity dimension.

Quantity–Quality Interaction

Becker and Lewis (1973) and Willis (1973) added a new twist to the quantity–quality model. They assumed that parents view child quantity and quality as substitutes and they treat all their children equally, in the sense that child quality is the same for each child. Expenditures on their children's human capital acquisition and monetary transfers to their children represent expenditure on child quality, which is the *product* of the number of children, quality per child and the full cost per unit of child quality (which is discussed later). This model can be generalized to incorporate costs of the number of children that do not depend on child quality and costs of quality that do not depend on the number of children. As an example of the former, a decline in the cost of averting births, say because of the introduction of the oral contraceptive pill, would increase the marginal cost of a birth without affecting the marginal cost of child quality.

The product in the budget constraint implies that the cost (or 'shadow price') of an additional child is proportional to the level of child quality, and the cost ('shadow price') of raising child quality is proportional to the number of children parents have. As a consequence, there is an important interaction between family size and child quality. Suppose, for example, that there is a *small* exogenous decrease in fertility, say because of lower contraception costs. This lowers the shadow price of child quality, which in turn raises child quality, which raises the shadow price of children, which lowers family size further, and so on. Similarly, a higher return to human capital increases investment per child. It raises the shadow price of children, which lowers family size and the price of child quality, thereby raising child quality further. Thus, increases in the returns to human capital investment associated with technical change may lead to simultaneous *large* reductions in fertility and increases in human capital investment in children. This is consistent with important stylized facts of economic development and links family economics with the study of economic growth and development (Rosenzweig, 1990). The interaction between child quality and fertility does not derive from assuming that child quality and quantity are *close* substitutes for one another. Indeed, just the opposite must be the case, because if both fertility and child quality are to be nonzero, then they cannot be close substitutes. Thus, family size can be highly responsive to changes in prices and incomes, even though children have no close substitutes.

The quantity–quality interaction may also produce a 'high fertility–low child investment trap,' in which low quality produces a low price of children, high fertility and a high shadow price of child quality. Higher parents' income increases fertility and the price of child quality, keeping child investment low. It may take some policy or technological development that alters the prices of quantity or quality independently, such as a family planning intervention or a large increase in the return to human capital investment, to 'spring the trap.' Once sprung, if the quality income elasticity exceeds the one for quantity, then the ratio of quality to the number of children rises with higher income, thereby increasing the shadow price of an additional child relative to the shadow price of child quality. The substitution effect induced by this increase may be sufficiently large to produce a decline in fertility when income increases, even though children are 'normal goods,' in the sense that parents want more of them when parental income increases.

Child Mortality and Fertility

The ultimate manifestation of low child quality is a child not surviving to adulthood. Scientific advance or a policy intervention, such as better water supply or public health, increases the probability of child survival, which has conflicting impacts on fertility. On the one hand, because a cost may be incurred by a birth regardless of whether or not the child survives, lower child mortality reduces the price of a surviving birth, thereby encouraging *higher* fertility. But if parents can influence the chances that their own children survive to become adults by spending more on each child, then it is *possible* that better chances of child survival reduce fertility, provided that exogenous factors affecting child survival substitute for parents' expenditure (Cigno, 1998). Such a relationship may help account for the 'demographic transition' – the change from a high fertility–high child mortality environment to a low fertility–low mortality one.

Another possible mechanism that may cause improvements in child survival to reduce fertility was proposed by Sah (1991). He argued that parents may wish to have more births when survival chances are low, because some may die before adulthood and they will not have enough time to replace them in their fecund period. This 'hoarding effect' on fertility dominates the fertility-discouraging effect from a higher price of surviving birth when the child mortality risk is high if parents are sufficiently 'risk averse,' or there is a 'target fertility level.' If either of these conditions holds, better survival chances for children tend to reduce fertility because their incentive to practice such 'hoarding' is less.

Fertility and Support in Old Age

If people do not have access to a capital market, an extended family transfer network including three generations at different stages of life could substitute for one (Cigno, 2000). In effect, it arranges 'loans' to its young members from its middle-aged ones and enforces repayment later when the young borrowers have become middle aged and the middle-aged lenders have become old. Because everyone needs the family transfer rules to survive in old age, the prospect of receiving no support from the family in old age deters any member from disobeying the rules, causing the rules to persist over generations until there is a change of circumstances outside the family. These rules also determine fertility. Larger transfers to the elderly relative to those to children increase the fertility required to sustain the family system.

The opening of a capital market with a sufficiently high interest rate offers the middle aged an alternative to this family transfer system. A threat of no support from the family in old age is no longer a deterrent, because they can make their own provision for old age through the market. In broad terms, this prediction is consistent with the observation that the growth of the financial sector, or the introduction of a state pension system, tends to coincide with a sharp decline in private transfers from the middle aged to their elderly parents and a fall in fertility. The fact that childbearing does not cease, suggests that the demand for children is not entirely derived from the need for transfers from them to finance consumption in old age.

The Cost of Children

Consumer theory tells us that, like any other price, a higher full cost of child quality per unit ought to reduce both fertility and child quality. Elucidation of the factors affecting this cost was another important contribution to the economics of fertility. In particular, it acknowledged the key role of parental time, especially the mother's, in the rearing of and investment in children. The foundations for this analysis were laid in a paper by Mincer (1963) and in Becker's (1965) theory of time allocation, and Willis (1973) built on them in his analysis.

The concept of 'household production' is important in understanding what influences the cost of child quality. Following Becker (1965), the parents' standard of living, the number of children and quality per child yield satisfaction to the parents, but they cannot be purchased directly in the market. Rather, the parents' standard of living and child quality are both produced within the household by combining parents' own time and purchased goods and services. It is the costs of these inputs that determine the cost of child quality relative to the cost of the parents' living standard. Parental time in the production of child quality is disproportionately the mother's time, and the rearing of children is assumed to be *time intensive* relative to other home production activities. That is, the proportion of the total cost of producing children represented by the value of the mother's time input to children is larger than the proportion of the total cost of producing the parents' standard of living represented by the value of her time input to that production. Thus, the unit cost of child quality relative to the cost of the parents' living standard is directly related to the mother's cost of time. If she has ever been in paid employment, her cost of time is the wage she could earn in employment (i.e., her forgone earnings). The higher her wage, the higher the cost of quality per child and of an additional child.

This analysis suggests, therefore, that men's and women's wages should have different effects on fertility. Higher wages mean higher income for the parents, encouraging them to have more children and to invest more in the human capital of each child or to make larger monetary transfers to them (i.e., higher quality). But higher wages also mean more income lost by those caring for children and investing in their human capital. Because child-rearing is mainly done by the mother, higher women's wages raise the opportunity cost of a child as well as increasing family income, while higher men's wages mainly affect childbearing through their effect on the couple's income. If the opportunity cost effect of women's wages is larger than their effect on fertility through higher family income, then higher women's wages reduce family size and child quality. It then follows that an increase in the ratio of women's to men's wages would reduce fertility.

In this model, the fraction of the woman's time supplied to the labor market is also a choice variable, which depends on the wage that the woman can earn and her partner's wage. There would tend to be a negative correlation between family size and the fraction of their life they spend in paid employment. This is a correlation between two choice variables. Variations in each partner's wages and in tastes drive both variables.

Purchased childcare can weaken the link between a woman's wage and the cost of an additional child. In Ermisch (1989), it is treated as an increasingly imperfect substitute for the mother's time in child-rearing as the amount of it increases. Mothers with high wages tend to purchase a much larger proportion of childcare time. For them, higher wages have less effect on the cost of children, making it more likely that a higher wage increases fertility by raising family income. Similarly, in countries with heavily subsidized childcare, mothers contribute much less of childcare themselves, making it more likely that women earning higher pay have larger families. At low to moderate levels of wages, a higher mother's wage reduces fertility, but its negative impact attenuates as her wage rises, or the price of childcare falls, because mothers purchase a larger proportion of childcare time under these conditions. The impact of the price of childcare on fertility displays a similar interaction, becoming more negative as the mother's wage rises.

Nevertheless, when examining changes in fertility over time, the cost of purchased childcare and women's wages tend to move together, because women's labor is such an important input to the provision of childcare services. Thus, over time women's pay relative to men's and fertility should be negatively related, because higher women's pay raises the cost of children.

Dynamic Fertility Models

The theories discussed so far are 'static' in nature, the relevant time unit being the parents' lifetime. In order to consider decisions about the timing of births, imperfect fertility control, divorce risk, or the consequences of unexpected outcomes like birth-control failure or child mortality, a dynamic model is needed. First, some features of dynamic life-cycle theories are discussed, and then a model of fertility dynamics across generations is introduced.

Life-Cycle Dynamics

Dynamic models incorporating a sequence of decisions and imperfect, costly fertility control are more realistic than the static theories discussed above. Their predictions often depend on what is assumed about parents' ability to borrow and save. One of two polar assumptions has been made in the literature: either parents can borrow and save as they choose ('perfect capital markets') or they cannot do so at all (i.e., they must consume all of their current income).

In one of the earliest dynamic fertility models (Heckman and Willis, 1976), a couple's fertility is controllable by the contraceptive strategies they adopt, but control is not perfect. Because it is assumed that couples start obtaining satisfaction from children as soon as they are born, they wish to have their children early. Couples may, however, find it best to adopt a 'precautionary' contraceptive strategy early in their partnership in order to reduce the risk of having more children than they would have chosen to have, if fertility control were perfect and free. Such a strategy would result in postponing the age at first birth. If people cannot borrow or save, and their incomes rise with age, they would also wish to practice contraception in order to try to postpone childbearing to a time when the marginal benefit of income for parental consumption is lower (when they can 'better afford' children). Subsequent spacing of births (rather than having children as quickly as possible) would also be a response to this tension between their desire to have children early and the economic incentive to have them later, when parents' income is higher. The more rapid the increase in income with age, the greater the incentive to postpone the start of childbearing and to space births. In other words, births are timed in order to 'smooth' parental consumption over time.

Another common (but not universal) feature of dynamic models is allowance for the possibility that a woman's current participation in paid employment improves her future

earning capacity, and that absence from employment may reduce her pay when she returns to employment. Thus, a mother's absence from paid employment because of a birth has two costs: a loss of current earnings and a loss of future earning potential. An early example of such a model is that of Moffitt (1984).

Even when there are perfect capital markets, couples may choose to postpone childbearing because these opportunity costs of childbearing are high when the woman is younger and on the steep part of her career-earnings profile. Women in jobs in which work experience has less effect on earnings have less incentive to postpone. In addition, if the care of young children is particularly intensive in the mother's time, then a birth produces a temporary increase in the value of her time in the home to a level above the value of her time in the labor market, causing her to leave paid employment. It also increases the cost of an additional child, encouraging her to postpone the next birth until the value of her time declines sufficiently through the aging of the child. An unexpected birth, because of contraceptive failure, would generate similar incentives for the mother to leave paid employment temporarily and postpone having another child. Thus, there is an economic incentive to space births.

The risk of divorce can also affect fertility, and its effect is also associated with women's opportunity costs of childbearing in a dynamic framework. If, for example, more participation in paid employment raises future wages, the risk of divorce can encourage more paid employment by the mother during marriage and, by raising the cost of child quality, lower expenditure on children and lower fertility. These 'defensive investments' in future earning potential are undertaken to increase welfare later, when outcomes are uncertain because of the possibility of divorce (Weiss, 1997).

The death of a child encourages its replacement, because the marginal benefit of an additional child is likely to increase substantially when a child dies. Replacement makes a woman's number of births increase with the experience of child mortality. Unless child mortality is expected when the mother is older, replacement is a better response to child mortality risk than 'hoarding' (discussed earlier) because the latter involves a larger deviation from what the parents would have done in the absence of child mortality. Wolpin (1984) was the first to incorporate uncertainty about child survival into a sequential, dynamic fertility model, which permits analysis of replacement in response to child deaths and of the effect of infant mortality risk on fertility.

Detailed surveys by Hotz et al. (1997) and Schultz (1997) discuss the empirical strategies for applying the theories discussed above and the results of many empirical studies.

Easterlin's Relative Income Hypothesis

In Easterlin's (1980) view, an important factor affecting a young couple's willingness to marry and have children is their outlook for supporting their material aspirations. If they expect their earning potential to be high relative to their aspirations, they will be more optimistic and will feel freer to marry and have children. If they expect that they will find it difficult to achieve the standard of living to which they aspire, they will hesitate to marry and have children. The ratio of the couple's potential earning power to their material aspirations is called their 'relative income.'

A person's material aspirations are formed through experience; for a young person, the primary relevant experience is the standard of living experienced in his/her parents' home. Young people's expectations concerning their earning potential are largely shaped by their experience of working.

A person's relative income may be related to the size of his/her generation relative to the size of previous generations. There are important differences between the characteristics of new labor force entrants and experienced workers. The former have not yet acquired a high level of skills and are engaged in a considerable amount of job search with consequent high-job turnover. Older workers are more skilled and occupy career jobs with relatively low-job turnover. As a consequence of these differences, the ability to substitute between young and older workers is limited. Thus, when young workers are scarce relative to older workers, their wages are higher relative to older workers and their chances of upward mobility improve. When they are in relative abundance, their relative wage declines and their promotion chances deteriorate. If there is a steady growth in labor demand, the earnings of young people (say, aged 15–29 years) relative to older people (say, aged 30–64 years) tends to be inversely related to the number of young people relative to older people ('relative generation size'), which suggests that their relative income also moves inversely with relative generation size.

The relative income theory of fertility would then lead us to expect that people from smaller birth cohorts would have higher fertility than people from larger cohorts. If couples feel constrained to choose family size within certain limits, say two to four children, then 'scarce' generations, who start childbearing earlier because of their favorable economic prospects relative to their material aspirations, would cut back later as they reach their upper limits, and people from 'surplus' generations would catch up later to attain their lower limits. Such behavior tends to make the fertility rates of women of different ages (different generations) move together. The period total fertility rate would then also move inversely with relative generation size, and it would fluctuate much more than completed family size.

Nonmarital Fertility

The rising proportion of births outside marriage in many countries has produced a shift away from the paradigm of a couple making fertility decisions as a single entity. It suggests that men and women should be treated as individual agents in fertility decisions. Higher divorce rates would reinforce such a treatment.

The process of finding a spouse is one in which information must be gathered by costly search. These market frictions affect who marries whom, the gains from each marriage and the distribution of gains between spouses. Marriage market frictions open the possibility of a marriage market equilibrium in which there is childbearing outside marriage (Ermisch, 2003: chapter 7). When a man and women meet, the man can choose to marry the woman, or not, if she will accept him. While a woman faces the same choice when she meets a man, she can

also choose to have a child by the man and then raise it without the father. Depending on the amount of support from the father or from the social welfare system, a woman's welfare when raising a child by herself may be greater than what she obtains when single and childless. But there are also costs in terms of marriage market prospects associated with raising a child alone. A single woman with a child may find it more difficult to contact potential husbands while looking after a child. Taking this perspective, a woman who contacts a man whom she does not wish to marry, or who will not marry her, would choose to have a child by the man if the short-run gain exceeds the long-term costs in terms of her marriage prospects. Those women who expect to obtain a significant increase in welfare when they marry suffer a greater long-term cost by having a child while single than women whose marriage prospects are such that they expect to gain little from marriage. Thus, women with poorer marriage prospects are more likely to have children outside marriage. If marriage prospects are correlated with education or potential income, then low-educated or low-income women would be the ones that have children outside marriage.

Similar predictions are produced in a model without market frictions in which people either marry or remain single forever. Willis (1999) shows there can be what he calls an 'out-of-wedlock equilibrium' in which men with low incomes seek to father children outside marriage and women oblige them in preference to remaining childless. If the number of women exceeds the number of men and if women at the lower end of the income distribution have incomes, which are sufficient for them to want to raise children with their own resources (including transfers from the welfare system), then fatherhood outside marriage would be free. If low-income men can father children by more than one woman, nonmarital fatherhood may be more advantageous for them than forming a union with a low-income woman, even though the mother and child would be better off in the union. The single low-income mothers gain by becoming mothers rather than remaining childless. Thus, both theories explain nonmarital fertility as a rational choice by low-income men and women, while at the same time higher income couples choose to have children within marriage.

There has been little theoretical analysis of childbearing within cohabiting unions, which has grown in importance in many countries. In unions that are expected to have a short life, it may be akin to the analysis of nonmarital childbearing discussed above. More generally, it shares some features of the analysis of marital fertility, but there are also unique attributes of cohabiting unions that are probably important for fertility decisions. One is their high risk of dissolution (see discussion of divorce risk in Section Life-Cycle Dynamics). In light of it, it is important to treat the cohabiting couple's fertility decision as problem of choice under uncertainty in which each partner is an individual agent whose preferences, expectations, and resources influence the decision. These are new challenges in the economic theory of fertility.

Family Theory: Economics of Intergenerational Relations

Abstract

Voluntary transfers between different generations of the same family may be attributed to either altruistic or nonaltruistic motivations. There is evidence that a substantial part of these transfers, including some apparently altruistic ones, are actually part of an unspoken deal involving three generations at a time.

In economics, the term 'transfer' denotes the delivery of money or other assets without counterpart. That usually is or appears to be the case when giver and receiver are members of the same family. Taxes and government subsidies are referred to as (public) transfers if there is no direct link between what any particular firm or household pays in taxes, and what it gets back in subsidies. A gray area is represented by certain types of old-age pensions, where the size of the individual benefits received are related in some way to the individual contributions made, but the link is either weak or subject to change by political decision.
